NEW YORK.

LIST OF CONTRIBUTORS TO VOL. LI.

Abbott, Dr. George E., Coronado Beach, Cal.
Adami, Dr. J. G., Montreal, Can.
Allen, Dr. Charles Lewis, Washington, D. C.
Allen, Dr. Charles W., New York.
Allen, Dr. J. Q., Montrose, Col.
Allison, Dr. H. E., Matteawan, N. Y.
Allport, Dr. Frank, Minneapolis, Minn.
Amberg, Dr. Emil, Boston, Mass.
Anthony, Dr. Albert G., Syracuse, N. Y.
Armstrong, Dr. Herman L., Brooklyn, N. Y.
Ashmead, Dr. Albert S., New York.

Balleray, Dr. G. H., Paterson, N. J.
Bangs, Dr. L. Bolton, New York.
Banister, Dr. W. B., Fort Cook, Neb.
Barrie, Dr. George, Washington, D. C.
Bashore, Dr. Harvey B., West Fairview, Pa.
Beck, Dr. Carl, New York.
Beirne, Dr. N. P., Galesburg, Ill.
Bell, Dr. J. Malseed, St. Joseph, Mo.
Benoit, Dr. E. P., Montreal, Can.
Bird, Dr. U. S., Tampa, Fla.
Blair, Dr. V. P., St. Louis, Mo.
Blaisdell, Dr. Frank, Goffstown, N. H.
Bogardus, Dr. E. W., Poplar Ridge, N. Y.
Bonar, Dr. Allan Blair, New York.
Bostwick, Dr. W. W., Fordham, N. Y.
Boude, Dr. J. K., Washington, D.C.
Bowens, Dr. G. Jarvis, Norfolk, Va.
Boyd, Dr. Robert, Grand Cayman, W. I.
Bradley, Dr. William L., New York.
Brewer, Dr. George Emerson, New York.
Brodhead, Dr. George L., New York.
Brooks, Dr. Henry T., New York.
Brothers, Dr. A., New York.
Brouner, Dr. Walter Brooks, New York.
Brown, Dr. Geo. T., Euclid, N. Y.
Bruner, Dr. William E., Cleveland, Ohio.
Buck, Dr. Albert H., New York.
Budd, Dr. J. B., Two Harbors, Minn.
Bulkley, Dr. L. Duncan, New York.
Bull, Dr. Charles Stedman, New York.
Bull, Dr. William T., New York.
Bunce, Dr. Philip D., Hartford, Conn.
Campbell, Dr. Alexander Mackenzie, Detroit, Mich.
Cantrell, Dr. J. Abbott, Philadelphia, Pa.
Carrier, Dr. Albert E., Detroit, Mich.
Caverly, Dr. C. S., Rutland, Vt.
Chapin, Dr. Henry Dwight, New York.
Chase, Dr. D. D., Morrisville, N. Y.
Clark, Dr. Horace, Buffalo, N. Y.
Clark, Dr. L. Pierce, Sonyea, N. Y.
Clemesha, Dr. J. C., Buffalo, N. Y.

THE ESSENTIAL NATURE OF CROUPOUS PNEUMONIA.

BY ANDREW H. SMITH, A.M., M.D.,

NEW YORK,

PHYSICIAN TO THE PRESBYTERIAN HOSPITAL; PROFESSOR EMERITUS OF THE PRACTICE OF MEDICINE IN THE POST-GRADUATE MEDICAL SCHOOL.

THE study of pneumonia, which has been prosecuted with so much energy ever since the dawn of pathology as a science, failed until recent years to suggest any other conception of the disease than that of an inflammation of the lung, with its accompanying inflammatory fever. Here and there, it is true, the idea has been expressed that the fever is the primary affection, and that the lung changes bear some such relation to it as the rash of scarlatina, for example, bears to the fever that attends it. The term "lung fever" is a survival of this view. It has even been maintained that the process is essentially a form of erysipelas, modified by the peculiar structure in which it has its seat; and, again, that it is a herpes zoster of the lung, having a nervous origin.

But these suggestions found little encouragement, and the weight of authority remained in favor of regarding the disease in precisely the same light as an inflammation would be regarded in any other part of the body. So recently as 1866, the late Dr. Flint, in his work on the "Practice of Medicine," adopted the term pneumonitis, "in conformity with the plan of distinguishing inflammatory affections by the suffix itis."

Bacteriological investigation during the past few years has resulted in the general concession that pneumonia is of microbic origin, and the special organism has been recognized and isolated. But it is held that the rôle of the microbe is to set up a local process that is still regarded as an inflammation.

However, the moment we consider inflammation as having its seat in the lung, we are confronted by the fact that here is a condition not found elsewhere in the body (unless approximately in the liver); viz., a double circulation, one nutrient and the other functional. All our ideas of inflammation in general cluster about the circulation by which the part is nourished. To be identical, therefore, with the inflammatory process as elsewhere observed, pneumonia should interest primarily the nutrient blood supply which is derived from the bronchial arteries. We should find the walls of the air-cells swollen, infiltrated, broken down in places. In fact, in view of the intensity of the local process and the massive exudate by which it is characterized, we should expect very serious damage to the delicate structures involved. Yet the truth is that after a few days the exudate disappears and we find the cell walls completely intact. It seems, therefore, that the process must have to do chiefly with the functional blood supply, and that the exudation takes place from the pulmonary capillaries, while, the nutrient circulation remaining undisturbed, the integrity of the structure is preserved.

In this view the process could be called inflammation only by courtesy. The air-cells are filled with an adventitious substance under circumstances that favor irritation, and there is more or less loss of epithelium from their walls: but this is secondary and incidental. There is no such profound lesion of the intervesicular structures as would explain the local and general results.

The discovery of the pneumococcus has enabled us to say that pneumonia is an infectious disease, depending upon the action of this organism. This is a great advance, but it still leaves the questions open: How does the micrococcus bring about the local and general conditions? How does it find its way to the lung, and when it gets there how does it act? There is a hiatus here which I hope the discussion of this evening will do something toward filling up. Indeed, it is the chief object of this paper to draw out the views of those present upon these points, and to see if there cannot be framed a theory that will correspond with the known facts and afford a connected view of the successive steps in the pathological process.

There are only three channels by which the microorganism might reach the seat of its activity in the lung. These are the blood-vessels, the lymphatics, and the air passages. With regard to the first of these, it has been amply demonstrated that the pneumococcus may find its way into the blood-vessels, and may set up a peculiar action in localities that are shut out from all communication with the exterior of the body. Thus, it is sometimes found in the fluid of pericarditis and in the pus of meningitis, the lung not being at all implicated. We must therefore concede the possibility of its reaching the lung in this way; but is this the usual route? Against this supposition is the fact that in the vast majority of cases of pneumonia the local infection is strictly limited to the lungs, although, as we have seen above, the organism is capable of attacking other structures. Moreover, if we admit a selective action on the part of the lungs, whereby the coccus is attracted, as it were, to the pulmonary structure (as the gonococcus, for example, is to certain localities), we still have to account for the fact that, as a rule, the morbid process begins in a single focus in the lung and spreads from that as a centre, instead of attacking different places in the lungs, as it would be likely to do if the organisms were floating in the blood. When we add to this what the researches of Kanthack[1] prove—that, if in a case of pneumonia the pneumococci are found in the blood and can be cultivated from it, the prognosis is bad; while under usual conditions so large a proportion of cases of pneumonia terminate favorably—we have a strong probability, to say the least, that the blood-vessels are not the usual channel of infection.

As to the lymphatics, the same reasoning holds good, and, in addition, we have the extreme improbability that the organisms could pass the barrier of the lymphatic glands.

This brings us to the air passages as the most likely channel of infection. The provision of nature for preventing access of foreign material to the air cells is so complete that they are very seldom invaded by even

[1] London Lancet, 1896, p. 293.

the finest particles that are carried in the atmosphere. Doubtless this provision is operative to a very great extent in protecting the lungs from the ingress of pathogenic germs. These may appear in the mouth and pharynx, where the epithelium is of the pavement variety; but when they reach the point where the ciliated epithelium begins, the outward movement imparted by the action of the cilia opposes their further progress. But for this we should find all manner of germs disseminated over the whole extent of the respiratory tract, instead of being confined to the regions above the glottis.

But this protection is not absolute at the best, and is liable to be impaired by any cause that affects the bronchial mucous membrane. Thus the efficiency of the ciliary movement is lessened during the early dry stage of a common cold and in bronchial catarrh. But in any case there is no difficulty in admitting that micrococci existing in the upper air passages may, under favoring conditions, find a way open to the alveoli through the respiratory passages. This being so, and the pneumococcus being widely disseminated in the mouths of healthy persons and presumably in dried sputa outside the body, the access of such organisms to the air cells through the respiratory passages is a condition of infection which may be supplied at any moment.

As a corroborative of this view of the mode of access of the infecting germ, it is interesting to observe that as in two-thirds of the cases foreign bodies passing down the trachea find their way into the right bronchus, owing to its greater width, so we find in practice a very considerable preponderance of right-sided pneumonias, the result probably of the same anatomical condition by which germs on reaching the bifurcation in their passage downward are influenced to pass into the right bronchus rather than the left.

Passing now more into the region of theory, the following seems to me the probable course of events after a germ has become lodged in an air vesicle. First of all, the intruder excites a degree of irritation that involves the adjacent capillaries, separated as they are from the interior of the air cells by only the most delicate of structures. The result of this irritation is an exudation into the cell. Possibly the fact that the blood supplied to the pulmonary capillaries is venous instead of arterial may have something to do with this. The germ now finds itself immersed in a fluid most admirably fitted to act as a culture medium, and the temperature and the conditions generally are precisely those most favorable for its multiplication. Just what is observed in artificial cultivations outside of the body occurs in the air cell, and we soon have the cell filled up with exudate and the exudate swarming with pneumococci. The overflow from one cell starts the process in adjacent cells; a lobule filled with exudate overflows into the bronchiole leading to another lobule, and so on until an entire lobe becomes involved.

Meanwhile, just as in the artificial culture, a toxin is being formed, and as rapidly as it is produced it is taken into the circulation. Here again the anatomical conditions favor the morbid process. No arrangement that can be conceived would be more perfectly adapted to the rapid absorption of the poison. The transfer of this material into the blood produces the familiar symptoms of infection—the chill, the rise of temperature, the nervous shock. So long as fresh supplies of toxin are being formed, or, in other words, so long as the consolidation is spreading, so long the toxæmia will be maintained. But here again, as in artificial cultures, there is a limit beyond which the process cannot extend. A given quantity of a culture medium can maintain the life of a given number of germs only for a certain time. Beyond that time the changes produced in the medium render it unfit as a soil for the further growth of the organism, and the death of the latter puts an end to the process. With the supply of toxin cut off, the temperature falls. If the invasion has been regular and rapid, coming to an abrupt termination with the complete consolidation of the lobe, the supply of toxin will cease abruptly, and we shall have defervescence by crisis. If, on the other hand, the effusion into the air cells has been gradual and the process of consolidation slowly carried forward, the supply of toxin will continue in one part while it fails in another, the process will be prolonged, and the defervescence will be by lysis.

This does not exclude the theory of the production of an antitoxin. Indeed, numerous observations, and especially those of the Klemperer brothers, of Munich, go to show that a transient immunity is created by an attack of pneumonia, and that this immunity may be transferred to another subject by serum inoculation. This could scarcely be explained except on the theory of an antitoxin, and I can see no obstacle to accepting both theories in explanation of the clinical phenomena in question. In other words, the defervescence may be the result of two causes—the failure of the supply of toxin and the action of an antitoxin.

It will be urged against this view of what takes place in the pneumonic lung that there is no necessary relation between the amount of lung involved and the degree of toxæmia. This is emphatically true as a simple proposition; but in this, as in all other forms of toxic infection, different persons show remarkable differences in susceptibility to the poison, and at the same time the poison itself varies extremely in virulence. To this we may add that in all probability there are comparatively few cases in which a single form of organism is responsible for the affection, most exhibiting two or more varieties of micrococci with differing infective energy. Furthermore, accepting the theory of an antitoxin, the period at which the formation of this substance begins in a given case and the rate at which it progresses become at once factors in determining the general condition of the patient at a given time. Keeping these points in view, we may safely say that, other things being equal, the systemic impression will be closely proportioned to the extent of the local invasion.

Occasionally in the progress of a pneumonia gangrene of a portion of the lung takes place. We may assume that in these cases a branch of the bronchial artery becomes involved in the process, thus shutting off the nutrient circulation from the corresponding area of lung tissue. That this does not occur more frequently shows how passive is the rôle played by the pulmonary parenchyma. A process of less intensity involving the nutrient vessels would account for the permanent changes which are found in chronic pneumonia, which is a true inflammation of the lung.

Suppuration with the formation of abscesses in the lung tissue is now and again observed. This is probably due to a mixed infection, in which other pathogenic germs take part with the diplococcus and produce a more intense degree of local irritation.

The evolution of new germs having ceased, and the system having recovered in a measure from the depression of the toxæmia, the process of removal of the exudate from the air cells begins. This is accomplished chiefly by absorption. In the course of a few days, if all goes well, the cell is entirely relieved of its contents, its walls remaining intact and ready for an immediate resumption of function.

The sum of the argument, finally, is that from its peculiar construction the lung is enabled to afford a field for bacterial culture and to supply a culture medium, and this without calling upon its own nutritive resources or directly compromising its own tissues. It

is the fact that in the lung there are empty spaces accessible to bacteria, and separated from an unlimited blood supply by only the thinnest and most permeable wall, that makes the phenomena of pneumonia possible. It is the further fact that the framework between these spaces has its own separate blood supply apart from the vessels involved in the pneumonia process that prevents a sweeping destruction of lung tissue.

In rare instances in the course of pneumonia there is a simultaneous infection of a number of serous or synovial membranes. Such a case was the subject of editorial comment in the New York MEDICAL RECORD for September 5, 1896. In this example there was effusion into the pericardium, into both pleura, into the peritoneum, into the knee-joints. The fluid in each of these situations was found to contain an abundance of pneumococci. In seeking for an explanation of such general infection, we should need to go no further than to assume a destructive process, however limited, by which the interior of an air cell should be made to communicate with an adjacent vessel, thus throwing the contents of the cell, teeming with bacteria, into the general current of the circulation.

In conclusion, I grant that much of what I have said is of the nature of pure speculation. The evidence is mostly circumstantial. To what extent it will bear examination will, I hope, be determined by the discussion that is to follow.

Should the theory be sustained, if only in outline, it would follow that the most natural direction for therapeutic effort would be that of attempting to render the exudate inimical to the development of micrococci.

This might be effected by acting through the blood, but better and more directly by inhalations. Stipp, Theodore Clemens,[1] and others have reported very remarkable successes from inhalations of chloroform. It is true that these were employed with a view to the sedative and anodyne effects, but insomuch as chloroform is a very efficient germicide (a small fraction of one per cent. being sufficient to sterilize a culture medium), it may well be that the hastening of the crisis so generally observed was due to this action rather than to the one the observers had in view. If given before the air cells were completely occluded, the chloroform would come into immediate contact with the exudate, and sterilization of the latter and arrest of germ development would result.

In the single instance in which I have employed this treatment, defervescence took place on the fourth day, forty hours after the inhalations were begun. The patient was a lady, seventy-five years of age, and the pneumonia occupied the lower half of the left lung. The chloroform was diluted with half its bulk of alcohol, and was given for ten minutes of each hour. So much air was admitted that the patient experienced nothing more than a decided drowsiness during the inhalations and lasting for a few minutes afterward.

Possibly other agents of a character to be inhaled might be substituted for chloroform with advantage, but thus far this has been the only agent employed.

As, according to Sternberg, the pneumococcus lanceolatus will not grow in a medium that contains the slightest trace of a free acid, it may be that the addition of a volatile acid—such, for example, as acetic—in quantity not sufficient to be irritating, would add to the efficiency of the inhalation.

Intracranial Lesions of otic origin are diagnosticated in only two-thirds of the cases, according to post-mortem statistics gathered by Weichselbaum in Vienna, and based upon over forty thousand autopsies. Four and one-half per cent. of deaths were found to be due to this cerebral affection.

THE SURGICAL TREATMENT OF TUBERCULOSIS.[1]

By HOWARD LILIENTHAL, M.D.,

ASSISTANT SURGEON TO MOUNT SINAI HOSPITAL, NEW YORK.

MANY years before the discovery of the tubercle bacillus, scientific men had come to the conclusion that tuberculosis was not a uniformly incurable disease. Cicatrices and calcified foci were found in the lungs post mortem in subjects dead from other diseases, while enlarged and "scrofulous" lymph nodes, with or without suppuration, as well as joints affected with "white swelling," were frequently cured under general treatment directed to body nutrition, together with local measures whose object was rest to the diseased part. The treatment was empirical, but was based upon common sense. The knife was resorted to when abscesses were pointing. When a joint was pretty well disintegrated, some of the bolder surgeons performed resections, which frequently were unsuccessful and were followed by amputations. Operations for bone inflammation when abscesses had not formed must have been rare.

Following the wonderful discovery of Koch, numerous investigators found that a large percentage of lymph-node joint and bone disease was in reality local tuberculosis, while there was scarcely any tissue of the body which might not be the seat of the infection. The clinical recognition of the trouble became more and more a matter of certainty, and our efforts to eradicate the morbid process grew more effective, because they were undertaken with a fuller knowledge of what was to be achieved.

At the present time it is safe to say that tuberculosis is amenable to treatment in direct ratio to our ability to attack it locally. Thus, tuberculosis of the lungs is much more difficult to cure than tuberculosis of the knee-joint, while tuberculous meningitis is an almost hopeless condition. In this respect the disease differs widely from another disorder, the lesions of which often resemble it. I refer to syphilis, the manifestations of which, though often favorably influenced by local treatment, are almost uniformly helped by systemic medication.

The local treatment of tuberculosis must depend largely upon the tissue involved and its accessibility. The methods advocated in this paper are those which in my own experience have led to success. For the most part they are not original, though their application in some cases may be so called. I shall say a few words on the treatment of tuberculosis of skin, bone, joint, kidney, and pleura.

In tuberculous skin disease, whether it be lupus or some other form of ulceration, we have the malady in an easily accessible region. Unless a deforming scar is feared, a wide excision or a thorough and, if necessary, repeated burning with the thermo-cautery will usually stamp out the trouble. Should the disease show itself in the skin of the face, it is well to test non-deforming measures for a short time before resorting to such radical treatment. I have found that it is possible to secure perfect healing with minimal cicatrization, when the ulcers are not too large, by the following means: The diseased parts are to be enveloped for twenty-four hours in a soaking wet dressing of some bland fluid, a weak aluminium acetate lotion being my favorite. At the end of this period the skin is carefully cleansed with ether, and then a solution of iodoform in contractile collodion is painted upon the diseased area. More collodion mixture should be applied daily for several days, according to the progress of the case. If improvement ceases or retention of discharge under a crust is present, then another wet

[1] Read November 28, 1896, before the Howard Medical Society of New York.

dressing must be applied for a day, when the iodoformized-collodion treatment is to be continued. I look upon it as very important that the collodion should be unmixed with castor oil, and that its contractile qualities should be most pronounced, so as to blanch the skin. The treatment succeeds partly by reason of the iodoform, and partly because the minute crypts and tracts of ulceration are closed by their own walls, which are pressed together by the contractile film and no longer invite retention.

Tuberculosis of bone must be differentiated principally from neoplasm and from syphilis. The evening temperature and the existence of marked pain and tenderness, besides the history of the case, will usually exclude neoplasm; but it is not always possible before operation to exclude syphilitic osteitis with suppuration at the centre.

To read an exhaustive paper on the treatment of bone and joint tuberculosis would occupy the time of many meetings of our society. I shall therefore confine myself to a few points.

Just as in consumption of the lungs there is first a period of hyperæmia, then consolidation, and, finally, necrosis and ulceration, so in tuberculous osteomyelitis we have an analogous process terminating in necrosis and abscess. Again, as in lung tissue, so also in bone tissue, the process may be checked before pus formation. The disease then will exist as an inactive focus, which may for a long time cause no pain and no inconvenience. This spot of disease may, however, become active upon slight provocation, and tissue destruction may then progress with great rapidity. Our treatment must, therefore, be carried out according to the location of the trouble with regard to surrounding important structures. Tuberculosis in the shaft of a bone may often be treated for a long time by rest and the local application of cold, in the hope that the process may become dormant; while if we know that there is active bone disease near a joint which is as yet unaffected, the indication is for surgical interference before the joint becomes diseased. When the process in such instances is confined accurately to isolated foci, they may be removed entire, only healthy tissue remaining. It has repeatedly been my fortune to prevent by operations of this kind the danger of joint involvement, just as one may prevent peritonitis by the early removal of an inflamed but non-perforated vermiform appendix. Indeed, I have operated in such cases when the focus was in such a location as to make an accidental opening of the joint during the operation unavoidable. An iodoformized gauze plug sealed this opening, however, and was kept in place till granulation of the wound was well established, the articulation escaping involvement.

When infection commences in the synovial membrane of a joint, there is first a pouring out of fluid, which fills the sac more or less tensely. If this fluid is non-purulent, a speedy cure, which may remain permanent, may sometimes be effected by antiseptic irrigation with a five-per-cent. carbolic solution, afterward in its turn washed away with normal salt solution. For this purpose two sterile cannulæ are inserted into the joint, the liquid running in at one and out at the other. The little operation must be performed with scrupulous care, however, because of danger from sepsis, and also because carbolic acid left in the joint may, particularly in children, give rise to constitutional symptoms.

When a joint is destroyed so that it function is permanently gone, resection of the bones, with thorough clearing away of diseased capsule, usually gives promise of a useful limb. This is more necessary when there is evidence that tuberculous bone cavities are in direct connection with the joint.

I do not mean to be too sweeping in advising the excision of joints, because it is well known that mechanical treatment, which usually means local rest by means of apparatus, will often accomplish much. I would like, however, to say a word in particular on excision of the knee for tuberculosis in adults, because I believe that this operation is not performed often enough.

Frequently it happens that the patient himself, preferring anything to a surgical operation, will for years nurse a limb which is a constant menace to his life. Such a knee will be partly serviceable for a few weeks at a time, when, owing to a slight blow or an overstrain, the disease lights up afresh and the patient goes to bed or makes use of a splint and crutch. The general health suffers, and even on the good days the thermometer shows elevation of temperature. The only thing to hope for in such cases is a stiffening of the joint, and it is true that proper fixation will often accomplish this result. If, however, there is ever so little motion, the cure is not complete, while the danger of an awakening of the dormant tuberculosis by a slight blow or other injury is ever present. A patient with such a knee is truly an invalid, being able to walk but a short distance at a time, in constant fear of injury, and acquiring the characteristic tuberculous pale and waxy look. To such a one excision will prove the greatest of blessings. Usually within three months from the time of operation he will be able to walk comfortably, and, confidence being restored, exercise becomes once more a pleasure. The color returns to his cheeks, the entire expression changes, and life is again worth living. I have found this class of patients more grateful than any others—even those who have gone through a life-saving operation for acute disease, because they are rescued from a life of suffering and are made healthy, while the robust man who is suddenly stricken with a life-threatening ailment often enough chafes at the necessary restraint and the possible deformity following his recovery.

When the kidney is the seat of tuberculosis, it should be treated largely according to the type of disease present. If there is perinephritic abscess, evacuation of the pus sac is in order. When we have true kidney abscess with or without stone, it is far safer to get rid of the offending organ, unless our patient has the misfortune to suffer from bilateral disease. When there is no abscess, but bloody urine with pus and bacilli, the case may be not so hopeless, for it shows that the site of disease is washed by the urine, the ulceration being, as it were, superficial. I have treated one man, thirty-six years old, who had long-continued hæmaturia with enormous numbers of tubercle bacilli, and both of these signs disappeared completely after a rather long-continued course of diuresis by the ingestion of water. This man disappeared from my observation after about three months' treatment with Klebs' tuberculocidin, and I afterward learned that he had gone to a hospital, where operation was proposed and was by him refused. Three years later, when I had long looked upon him as dead and buried, he walked into my office apparently well, merely to show himself. I examined him with interest, and took a specimen of his urine, which was normal. Careful examination failed to disclose the presence of bacilli.

I shall conclude with the brief report of a case of pyothorax, which came under my observation on November 2, 1892. I was called in consultation by the patient's physician to see J. H——, a little girl, four years old, whose right chest was full of pus. The subjective symptoms had been slight and the temperature not high, the existence of the disease having been revealed in the routine examination. The next day we operated, making the incision well down and slightly back of the post-axillary line. No rib resection was done. The cavity was washed out with five-

per-cent. carbolic, then with plenty of Thiersch's solution, and two rubber tubes were inserted. A very thick dressing was applied, after we had by experiment determined in which position of the child's body the Thiersch's solution injected would best run out. It was my advice to adopt in this case the method of Koenig, not to wash out again but to leave the original dressing in place as long as possible, placing the child in the position to aid drainage, as determined at the operation, for several minutes once every hour. The treatment was well carried out, and no change of dressing was made for six days. In ten days more the child was perfectly well, and the wound had closed permanently.

I examined a specimen of the pus, by boiling it with a sodium-hydrate solution and concentrating the sediment. It contained many tubercle bacilli. The brilliant result can be explained by supposing that a fairly complete disinfection took place at the operation, and that the lung expanded so quickly and completely as to leave but little space for stagnating pus. The drainage by gravity, according to Koenig, and the abstinence from irrigation after the day of operation, I consider of importance.

It is probable that, as our science advances, more and more remote portions of the body will become accessible for the employment of local remedial measures, and until a specific shall be discovered which will be to tuberculosis what mercury is to syphilis, it is perhaps well to work with the rule in mind, which I may be pardoned for repeating: Tuberculosis is amenable to treatment in direct proportion to the accessibility of the part involved.

LENTICULAR MYOPIA AS A CAUSE OF SO-CALLED "SECOND SIGHT."

By D. B. St. JOHN ROOSA, M.D., LL.D.,

NEW YORK.

A GREAT deal more is said among the laity than in the profession about the ability of old people to read without glasses. The reasons for this are not far to seek. Very many of the people who are able to read fine type in old age without glasses are simply short-sighted. The myopia, although it may have existed from a very early age, is not generally recognized by those who speak of their ability to see without glasses, and who think that their sight is rather better than the ordinary, because such persons are generally able to go about, see large objects, and even recognize faces at some distance, without glasses. They do not have a high degree of myopia. This apparent wonder is, therefore, not one to ophthalmologists, and no serious consideration is usually given it. Those who have not given optical defects any careful consideration, even if they be physicians or surgeons, may not know that a myope who requires, say, a glass of six or eight inches focal power to see objects well at a distance must necessarily, even in advanced age, be able to read fine type at six or eight inches from the eye, because the antero-posterior diameter of the eye is adapted to the divergent rays that proceed from near objects, and because this abnormal length more than balances the effects of time on the muscle of accommodation and the crystalline lens, which practically shorten the eye and cause presbyopia, with its necessity for convex glasses. But there is quite a number of cases, not myopic originally, in which the patient after middle life discards the ordinary glasses for presbyopia, and reads for years without glasses. Lenticular myopia occurs in such eyes: that is to say, the lens becomes elongated by swelling. This swelling, however, if it simply produce capacity to read fine type without glasses, is not attended with opacity: cataract does not occur, although, as is well known, all opaque lenses become increased in refractive power. The condition now spoken of is, so to speak, an abortive cataract, a swelling of the lens without opacity.

Since very few of these cases have been carefully observed, or, at least, since they have not been reported before the transition period or afterward, I publish the following, which illustrates what happens in all cases of this class:

Hyperopia, Presbyopia; Hyperopia becomes Myopia, with Ability to Read Fine Type without Glasses.—Sarah X—— consulted me on April 29, 1878, with reference to glasses. She was rather a delicate woman, of forty-one years of age. Her eyes were watery. She had worn glasses for reading for three years.

Vision was $\frac{2}{10}$ in the right eye, $\frac{2}{10}$ — in the left eye. With a glass of $+\frac{1}{36}$, the vision became $\frac{2}{20}$ in each eye, and with a convex glass of ten inches focal distance she could read No. 1 Jaeger at eight inches. These glasses did very well for eight years, when she again consulted me. She was then able to read No. 1 Jaeger at eight and three-fourth inches with her glasses. A glass of + 4 diopters was ordered, with which she could read No. 1 Jaeger at eight inches and ordinary type easily. No change was made in the glasses for looking at a distance, which were still serving her well.

On October 19, 1896, the patient again came under my observation. She said she had not used glasses for reading for more than a year, because she could read very easily without them. The vision in the right eye was $\frac{2}{15}$. With — 2 diopters it became $\frac{2}{30}$. In the left eye her vision was $\frac{2}{20}$, and with a — 3 diopter it became $\frac{2}{40}$. She had but half a diopter of corneal astigmatism, with the rule. With + 2 diopters she could read No. 1 Jaeger at eight inches with the right eye, being an increase in the refractive power of exactly that, as it was a glass of 4 diopters that she formerly used for reading. With the left eye she could read No. 1 Jaeger fluently at eight inches with no glass, and ordinary type very easily.

The ophthalmoscope showed absolutely no lesion—the lenses were clear, the retina was sound. It is reported as a case of lenticular myopia, occurring after middle life, producing ability to read without glasses. It is a fair type of quite a proportion of cases of second sight, although, as was said in the beginning, most old people who are able to read fine print without convex glasses are usually myopic, and have acquired no new capacity by the advance of age. Their congenital or early acquired myopia, due, not to swelling of the lens, but to a lengthening of the whole eyeball, balances the flattening of the eye (lessened refraction), known as presbyopia.

Metastasis of Carcinoma of the Uterus to the Vagina by Inoculation.—Niebergall (*Archiv für Gynäkologie*, B. liii., H. 3, p. 491) makes an interesting addition to a previous report of a case presenting carcinoma, sarcoma, fibroma, and mucous polypus of the uterus. Total extirpation had been practised on account of carcinoma of the uterus, from which a sarcoma had already been spontaneously expelled. The patient was subsequently quite well for more than a year and gained considerably in weight and strength. At the end of this time increased vaginal secretion and burning micturition were noticed. Examination now showed, at a point within the vagina where the margin of the speculum had rested in the former operation, a small ulcer, which after excision with the thermo-cautery proved to be a carcinoma of the same character as that which had been present in the uterus.

MALIGNANT ENDOPERICARDITIS, WITH RECOVERY.

By THOMAS LUTHER COLEY, A.B., M.D.,

[illegible] ASSISTANT IN THE MEDICAL DISPENSARY, HOWARD HOSPITAL, PHILADELPHIA.

MEDICAL literature contains a few well-authenticated cases of recovery from malignant endocarditis and to this brief array the writer wishes to add one more, as he believes, well-attested case, which was in addition a pericarditis and a myocarditis.

"From an anatomical point of view recovery is not impossible," Rosenstein[1] wrote twenty years ago, "especially when the process has not gone beyond the first stages. And even if an ulcer do form, it may heal to a scar and recovery thus set in, if general infection was not the result or the origin of the endocardial disease. As a matter of fact, however, there is no case of recovery on record, and after the diagnosis has been once firmly established the prognosis must be regarded as extremely unfavorable." Rosenbach[2] points out that the dangers are not determined by the presence of the bacteria or the fact that the ulcerations have attacked the valves, but by the circumstance of the patient being a pyæmic subject. He goes on to cite the reported cases of recovery, but believes these to have been mistaken diagnoses.

Probably no differential diagnosis the practitioner is called upon to make is fraught with more difficulty than certain of these cardiac cases. Many run their fatal courses without presenting any discoverable physical signs, and it is left to the necropsy to prove the existence of the typical pathological conditions.

Then, again, when the cardiac signs are present and the patient is in an apparently septic condition, is this condition one of true sepsis? What might be mistaken for a septic condition engrafted upon a simple endocarditis or even an endopericarditis? There might, for example, exist a coincidence of intercurrent inflammations of the lungs or serous membranes, typhoid fever, or, more commonly still, malaria. There is also the possibility of a simple endocarditis being complicated by some distant focus of suppuration giving rise to the septic condition in a case presenting all the typical physical signs and the constitutional symptoms of a malignant endocarditis.

The diseases which often perplexingly resemble the condition under consideration are typhoid fever and malaria. The fact of the various forms of onset led Brunton[3] to classify them according to type into cardiac, typhoid, pyæmic, and aguish. Bristowe[4] has reported a case in which there was a gradual onset for several weeks with an intermittent fever, which closely resembled and was mistaken for malaria. This terminated fatally. The classical form of the disease, with its abrupt onset, extreme prostration, remittent or intermittent fever, enlarged tender spleen, ecchymoses, and suppurating foci, must of necessity run a rapid and fatal course. Stern and Hirschler,[5] however, report a case of recovery after ecchymoses, and Pye-Smith[6] another in which emboli had formed in the various arteries and produced aneurisms.

Jaccoud,[7] greatly impressed with the varieties of type, distinguishes three forms of malignant endocarditis, or, as he prefers to call it, infectious. 1. The classical form above described. 2. A less sudden, less acute form. Prodromata continue for six or eight days. The periods of fever are at first intermittent, and, except the case presents the typical physical signs, the diagnosis is very difficult. We must, however, differentiate this form from typhoid and malaria, and from rheumatism on account of the vague pains in the limbs. It is well to remember that pain in the joints is frequently the expression of a septic process and not due to rheumatism. 3. The third form is still more difficult of diagnosis. For several weeks there are periods of intermittent fever. There are three or four days of fever and an apparent return to health; then the fever returns. It is this form which is especially liable to be taken for malaria, on account of the fact that quinine confirms the mistaken diagnosis, as the remission is naturally attributed to the effect of the drug. While Osler's dictum that a fever which resists quinine is not malaria is a good practical rule, it is thus seen that the converse is by no means true. Still, the onset in these cases is slower than that of either typhoid or malaria. Jaccoud formerly believed that there was a relation between the variety of fever and the particular microbic cause. Now, however, he does not believe that a constant relation exists.

Osler[1] has recorded two cases of endocarditis with intermittent fever in which the disease lasted ten months in one case and eleven in the other, both finally terminating fatally. In these cases there was a daily fever for many months, in which the temperature ranged from 102.5 to 104° F., occasionally preceded by a distinct rigor, more frequently by slight chilliness. Sweating, sometimes severe, followed the febrile periods. There was progressive failure of strength, with varying intervals of improvement. The physical signs were an apex systolic murmur and a dilated left heart. In both cases there was a development of embolic symptoms toward the close.

Many cases of malignant endocarditis resemble phthisis. The character of the temperature and often the facial aspect, the hectic flush, the prominent cheek bones, and great emaciation all tend to suggest tuberculosis. The exclusion of a primary source of this disease elsewhere, as from the lungs, carious vertebræ or sternum, leaves open the possibility of an idiopathic tuberculous condition, endocardial or pericardial. Hayem and Tissier,[2] discussing tuberculous pericarditis, believe that this form of the disease is usually and perhaps always the result of extension by contiguity, whether from a carious sternum or spinal column, or from an adherent and tuberculous pleura, or from tuberculous bronchial glands. Parker and S. West[3] both believe that purulent pericarditis may be primary, sometimes that it is not associated with suppuration elsewhere. Slev states that tuberculosis is almost as frequent a cause of pericarditis as rheumatism. Usually the infection comes by way of caseous mediastinal lymph glands and less frequently by way of the pleura. In a few cases it forms a part of the general tuberculosis of the serous membranes.

The effusion in these cases is variable, from plastic to that of liquid consistency and great amount. The fever, so Slev[4] believes, is very irregular, more so than in pericarditis as usually manifested, but this symptom can scarcely be of much value, considering the great irregularity of the temperature in malignant cases generally.

Sansom[5] records a case in which the diagnosis of ulcerative endocarditis was made and a good recovery followed the use of thirty-grain doses of sulpho-carbolate of sodium and inunctions of carbolized oil. While the valvular lesions which were supposed to depend upon an old endocarditis were not removed,

all the evidences of acute lesions in the heart and septic infection were entirely relieved and the patient left the hospital well. Not long afterward she again returned with symptoms similar to those of the previous attack, which were not relieved this time by the same treatment. The autopsy confirmed the diagnosis of ulcerative endocarditis. McClun[1] reports a case with recovery which was greatly benefited by inhalations of carbolate of iodine.

In certain cases of long-standing valvular lesions, markedly those of the aortic and sometimes of the mitral orifices, there occur attacks of valvulitis, which are frequently accompanied by a varied and often perplexing array of symptoms. Most frequently they fit into the symptoms of acute simple endocarditis and with careful treatment do well, but the duration is always protracted. More rarely the fever is intermittent, sweats are common, and even severe rigors may occur. Such cases may closely resemble malaria, and the exclusion of this and any other assignable cause for the prostration leads us to the conclusion that it is a slowly progressive malignant case. This is the variety of which Pepper and Stengel[2] have reported three cases and which the Germans know as chronic recurrent endocarditis. Quite recently I saw with Alfred Stengel, in the wards of the Philadelphia Hospital, a patient closely fitting this description. The man seemed to be very slowly convalescing after weeks of prostration. He had long suffered from aortic regurgitation. The myocardium or pericardium were affected but slightly, if at all.

Pepper[3] says: "I have repeatedly had reason to suspect that a febrile process which did not seem referable to a renewed valvulitis was due to an extension of inflammation to the intima of the aorta; and quite recently a case of mitral disease terminated fatally where during a course of several years there were outbreaks of repeated chills followed by high fever, subsequently to which areas of severe arteritis appeared, leading successively to aneurism of the popliteal, femoral, and axillary arteries. Embolism of the central artery of the left retina also occurred." This case with the one before cited illustrates the class well, but it is remarkable in its chronicity and the extensive changes in the arterial coats.

The history of the writer's case is as follows: Louis G——, aged twenty-six years, white, had suffered from varioloid when nine months old, and at six years from what the doctor pronounced and what seemed to fit the description of inflammatory rheumatism. At eight years he had a severe attack of scarlet fever. He never had seemed to rally completely from the rheumatism, and following this he was never able to join his companions at play without fatiguing rapidly and being attacked by spells of giddiness, palpitation, and dyspnœa. In these attacks everything would become momentarily black before him. As he grew up he seemed to grow stronger, but was always looked upon as a weak, nervous boy. He learned the trade of a leather-bag maker, an occupation which he was able to follow for several years without losing a day, despite the fact that it required him to stand upon his feet all of the time. The patient's facial aspect was one of deep anxiety. There were fibrillary tremors in the tongue and the muscles of both extremities. Ankle clonus could be elicited and there was marked hyperæsthesia. For some time he had complained of all the food he swallowed sticking in the œsophagus and being dislodged with difficulty. For one month he had grown alarmingly weak. He could not sleep at night, and would start suddenly out of his doze of disturbed dreams and clutch at his chest to relieve the feeling of precordial distress which seemed to have awakened him, a sensation which he described as one of tightness or constriction. He began to suffer from rigors of varying severity, followed by high fever and drenching sweats. Finally, a week before he was first seen, on November 14, 1895, he had been seized with an attack of syncope while about to rise from the dinner table. This was followed by a severe vomiting spell. A severe serous diarrhœa set in, in which the patient was at stool as often as fourteen times in six hours. Pains in the calves of the legs, the muscles of the forearm, the shoulder girdle, and the pectoral muscles now became marked. He had of late been complaining of these vague pains in the arms, which had not been severe. Attacks of syncope followed every effort to raise himself even slightly from the prone position.

On inspection, the emaciation was considerable, the superficial fat being very scant. The chest was flat and the supra-clavicular fossæ were deep. The left side was the more prominent, the strong diffuse apex beat being visible at the seventh rib, displaced downward and to the left. Epigastric pulsation was intense. There was also marked pulsation of the cervical vessels and of the right subclavian.

The skin was cold and covered with beads of sweat; there was also a diffuse pustular eruption, most marked on the face and thorax.

On palpation the forcible apex beat was communicated strongly to the hand and together with this a very pronounced thrill, which was not lost to palpation anywhere over the cardiac area. The spleen was much increased in size and exquisitely tender on pressure. It was plainly palpable with the subject in the recumbent position. The liver was not enlarged. There was a mild degree of intestinal tympany, but no tenderness over the right iliac fossa.

On percussion the note over the lungs was good. The heart gave evidences of great hypertrophy with dilatation. The apex was at the seventh rib, five inches from midsternum. The right border of absolute dulness extended to one and three-quarter inches beyond midsternum at the fifth rib. On auscultation of the apex a very loud pericardial friction was heard and felt. Change of position made this only slightly less audible. A double endocardial apical murmur could be made out. The systolic was well transmitted to the inferior angle of the scapula. At the pulmonary area there seemed to be blowing murmurs with both sounds, probably hæmic in origin. These were also heard over the pulmonary vessels. The second sound was much accentuated. At the aortic area there was heard a loud regurgitant murmur with much roughening of the first sound. When first auscultated the pericardial rub was so intense as almost completely to hide the pronounced endocardial murmurs, which were elicited and confirmed only after repeated examinations.

The tension of the arteries was very high. There was a typical Corrigan pulse, with its remarkably sudden recession. The carotids pulsated strongly and the heart sounds were well transmitted. The jugulars conveyed to the ear the double murmur and in addition received an impulse from the carotid arteries. The dysphagia mentioned above has been classed as a symptom of pericarditis and has been referred to the pressure on the œsophagus of the sac distended with fluid. Walshe takes the view that it is of nervous or dynamic origin. The fibrinous character of the exudate in this case, in which the dysphagia was such a prominent symptom, would serve to add weight to Walshe's view. It may be well in passing to refer to Pettit's observation that furunculosis may be a cause of malignant endocarditis. This patient had suffered from furunculosis for six weeks before his taking to

[3] Pepper: "American System of Medicine," vol. ii., p. 303.

bed. The severity of the condition of the stomach, with which the prostration began, grew rapidly, until at the end of sixteen days rectal feeding had to be resorted to. The already emaciated patient seemed to lose weight daily. The spells of dyspnœa accompanied by severe palpitation became more and more frequent. The pulse in these attacks was the typical gallop rhythm of the overtaxed and degenerating heart muscle. The heart impulse grew much weaker and the heart sounds were scarcely heard, although the pericardial friction, neessarily weaker, was still plain. The septic condition seemed in full control at this time. The rigors were more or less severe and were invariably followed by a drenching sweat and fever, which for many days reached an average of 103.6°, 104° F. being the maximum. The morning temperature was always subnormal, 97.6° F. being the lowest point reached. The patient passed from a condition of mild delirium into a comatose state, and could be aroused but with difficulty. For three days even the slightest medication by the stomach was impossible and hypodermic injections of strychnine and nitroglycerin were freely made and nutrient enemata given. Alcohol sponge baths were given frequently and very gentle massage practised. After the third day egg water was retained in very small quantities, and by almost infinitesimal gradations the stomach became more retentive. The hypodermic injections and the rectal enemata were kept up for eighteen days. Then followed a long struggle to nourish this patient, and, while at no other time was the stomach so persistently rebellious, spells of vomiting were frequent and seemed to thwart every effort to increase the patient's strength. In February, however, food was well borne and vomiting occurred but four times. In March there were but two attacks, and no others occurred during the convalescence. With the increase in the ability to retain food, milk was given in large quantities and alcohol was pushed until the patient was taking over one quart of whiskey a day without the slightest toxic effect. Besides the great irritability of the stomach, which the close nervous connection between the heart and that organ so readily explain, in the distribution of the filiments of the pneumogastric, the absolute inability of the patient to secure sleep had to be confronted. Gradually, however, improvement took place in spite of most discouraging drawbacks, and finally the patient was allowed to sit up for the first time on May 20th. He had been compelled to remain in bed from November 15th to this date. It is somewhat remarkable to note that in all this time he did not suffer from a single bedsore.

During the long course of this case fifteen blood counts were made and the amount of hæmoglobin was estimated. The results are appended and show graphically the alarming increase in the anæmia and a possible mild degree of leucocytosis. February was the month in which the limit of the disorganization was reached and the first increase in the blood count noted. From this time there was a progressive gain, clearly illustrated by the results of the examinations as well as by the patient's increasingly encouraging condition.

Four bacteriological examinations of the blood failed to reveal the presence of pyogenic micro-organisms. The urine contained albumin, the quantity varying in the repeated analyses. A slight hæmaturia occurred twice. Epithelial casts were present for months, but disappeared with convalescence.

The character of the temperature in this case accords in one important particular with the observations of a number of others. The height of the fever did not exceed 104° F. This is a fact frequently noted in these very chronic cases of malignant cardiac disease. The morning temperature was for some weeks invariably subnormal. Ophthalmoscopic examination revealed a pale physiological disc. There were no traces of retinal hemorrhage. There was some pulsation of the retinal vessels.

The severe serous diarrhœa with which the patient was seized early in his illness proved a formidable symptom. It, like the fever, was intermittent in type. For days he would be free from it and then an attack would come on suddenly. From January 20th to February 10th these attacks became frequent and most alarming in character. After this date they were more easily controlled. The question arose, What was the origin of this diarrhœa? It might have been purely nervous in type or again due to the septic condition. More likely still, it might have been caused by embolic infarcts. This was also the cause, without doubt, of the exquisite tenderness of the spleen above referred to. It is possible that capillary infarcts of the brain also occurred, thus accounting for much of the muttering delirium and varied nervous symptoms. However, the severe degree of cerebral anæmia together with the systemic prostration would also readily explain this condition. On July 5th the patient was allowed to go out of doors for a short time. His exercise was gently increased and by August 1st he felt able to perform light work. He had taken on flesh quite rapidly and at this date weighed one hundred and thirty pounds. This was an increase of four pounds over his usual weight in health. On inspection at this time the body was seen to be well nourished. The supraclavicular fossæ were shallow. There was good resonance over the lungs and fremitus was not increased. Inspiration was strong and slightly increased; expiration was normal. The apex was strong and slightly diffuse at the seventh rib, five inches from midsternum. There was a barely perceptible epigastric pulsation. The first mitral sound was strong and booming, with a powerful diastolic blowing murmur. The aortic first sound was strong and there was a marked regurgitant murmur. The pulmonary second sound was accentuated. The carotids and right subclavian arteries pulsated strongly. The pericardial friction, while it could still be heard, had lost its terrific intensity. This seems to grow less very slowly. The aortic regurgitation is causing no symptoms further than giddiness on the slightest over-exertion, thus keeping him constantly reminded of his danger limit. The fibrillary tremors in the calf muscles from which he had been a long sufferer, and which an observer has likened to the tremors of pseudohypertrophic muscular atrophy, have quite disappeared.

This case was treated with strychnine from the very start and the dose increased from one-thirtieth to one twentieth of a grain every two hours. When it became impossible to give this by the stomach it was administered hypodermically. Digitalis was faithfully tried,

but, not seeming to give any relief, was finally discontinued. To secure the possible good of antiseptic remedies, the bichloride of mercury was given in twenty-fourths, at first *t.d.* and then every four hours. It was from nitroglycerin that the most relief was secured. This was given in two drops of the one-per-cent. solution, *q.d.* Alcohol, as has been stated above, was pushed to its limit, and every effort made to sustain the patient by careful feeding, milk being depended upon in the main. The writer believes that much was also accomplished in this case by alcohol sponge baths and gentle massage. All efforts made to check the drenching sweats by agaricin, which has been so loudly extolled, and by camphoric acid and belladonna all failed utterly. Quinine was given in routine for many months.

We find in looking over the literature of the treatment that there is a great diversity of opinion as to the relative merit of a various host of drugs, and, as in every condition of which this may be said, we are forced to conclude that medicinal treatment is not satisfactory. Every reported case seems to be a law unto itself in this respect.

Jaccoud[1] believes in the use of salicylic acid for its antipyretic and antiseptic effect. Others recommend salicin as being less of a heart depressant. Quinine has its strong advocates, and yet Jaccoud believes it to be worthless; and Koryani[2] declares that no remedies have proven of value and directs symptomatic treatment. McClun's[3] patient recovered upon inhalations of carbolate of iodine and Sansom's[4] upon thirty-grain doses of sulphocarbolate of sodium and inunctions of carbolized oil.

William Russell,[5] of Edinburgh, advises antirheumatic remedies and iodide of potassium internally and blistering the precordia. Dreschfeld,[6] of Manchester, recommends large doses of quinine with arsenic. In general, however, there seems to be no especial relation between the reported cases of recovery and the remedies given.

The etiology of this attack is unquestionably dependent upon two factors—the rheumatic seizure in the patient's sixth year, with the subsequent history of weakened nerve and muscle force, and the frequent spells of giddiness, dyspnœa, and momentary blindness, all pointing to the fact that there was at this time an endocarditis set up which left the patient with an aortic lesion and weakened endocardium. Whether the malignant character of the endocarditis in the present attack was due to the furunculosis which, as has been said, was present, or whether this was merely the expression of the septic condition is an open question. The rheumatic pains before described may have been the expression of a renewed attack of this disease and the consequent cause of the malignant endocardial condition, or, again, these pains may have been of purely septic character.

The Effect of Drugs upon the Secretion from the Tracheal Mucous Membrane.—Dr. James Calvert (*Journal of Physiology*, 1896, xx., Nos. 2 and 3, pp. 157–164) concludes that: 1. Alkalies increase the secretion. 2. Potassium iodide increases the secretion. 3. Emetin also increases the secretion in a marked degree. 4. Saponin does not increase the secretion if given in small doses, while in large doses it causes diminution of the secretion. 5. Cold applied to the abdomen increases, while heat applied in the same way diminishes, the secretion.

DERMATITIS HERPETIFORMIS.

By ALBERT E. CARRIER, M.D.,

DETROIT, MICH.

Case I.—Mr. F—— was referred to me for treatment by Dr. Theo. A. McGraw, January 12, 1896. He was a well-preserved man, had always enjoyed good health, was over seventy years old, in good circumstances, and not in active business.

Four years ago he received an injury which resulted in an abscess of the tibia of the right leg at its lower third. An operation was made, resulting in cure. Nervous exhaustion followed the operation, and uneasy sensations have been present in the parts ever since. The family history is good. He has never had any disease of the skin.

The present attack began about three weeks before he came under my care, commencing as a severe pruritus of the arms, legs, and back of thorax, with pain in the hip, wrist, and ankle joints. The pruritus was followed in a few hours by erythematous patches from the size of a pea to that of a fingernail, appearing in crops. Twenty-four hours later vesicles appeared in the centre of the macules, spreading at their circumference until blebs were formed which occupied the whole site of the original lesion. When the blebs were ruptured an excoriated base remained. There were no lesions upon the face, nor below the ankles and wrists. The blebs when fully developed had tense walls, sometimes fluted, had clear contents, and were not surrounded by an erythematous border. Dark pigmented sites remained after healing. Severe pruritus attended the lesions.

The conditions as related had existed from the outbreak of the disease to the time he came under my care, new lesions appearing from time to time to take the place of those that disappeared. On my first examination I found, in addition to the blebs, large red, infiltrated, scaly plaques, covering the dorsal surfaces of both hands and looking like patches of chronic eczema. Itching in these plaques was intense.

The patient complained of a feeling of tension of the whole cutaneous surface; said that it felt as if the skin was creaking when in motion. The most prominent lesions, however, were the blebs. Mr. F—— was a man of good habits, a very moderate smoker, and a single glass of wine at dinner was the extent of his indulgence in stimulants. A very careful examination failed to bring to notice any pathological condition that would hold the relation of cause to the skin affection. Five days after he came under my care a change occurred in the character of the lesions, small red macules appearing and small conical papules; the lesions were grouped, and in places the papules were so closely set as to form dime to dollar sized plaques. The papules were of the color of the normal skin, but the plaques had a pinkish hue. Small vesicles in groups also appeared over the back and chest, but did not develop in the macules. The macules, blebs, and papules were distributed over the limbs and abdomen, while the vesicles were on the front and back of thorax. Pruritus was intense in all the lesions. The patient at this time presented very little healthy skin, there were pea to cherry sized blebs, excoriations where the blebs had been ruptured, and pigmented macules where they had healed; dime to palm sized erythematous macules; papules single, in groups, or forming plaques; vesicles single or in groups; excoriations; crusting of vesicular and bleb lesions—the whole making a most characteristic picture. Very little change occurred during the following week. At the end of this time the lesions were smaller in size on the chest and upper extremities,

[1] Read before the Michigan State Medical Society.

while they seemed to increase in size upon the lower extremities, several large blebs forming on the legs. From this time until March 23d the appearance of the skin remained about the same, new lesions appearing as the old ones disappeared: blebs, however, being fewer in number and much smaller, while vesicles were very numerous. At times the eruption would follow the course of a cutaneous nerve. At no time during the course of the disease were the palms, or fingers, or feet, or neck affected. On April 18th my patient sailed for Europe entirely free (for the time being) of his skin affection.

Case II.—Mr. A——, twenty-six years old, a merchant, a man of good habits, with a good family record, was referred to me by Dr. E. L. Shurly in 1889 for a skin disease that had troubled him over five years. At no time during this period had the skin been entirely free of the eruption. The lesions had been principally vesicular, quite small, dome-shaped, and clustered in groups of from three to a dozen, with clear contents. Pruritus always preceded the eruption from four to twelve hours and continued until the vesicles were ruptured. The sites selected for the outbreak seemed to be the extensor surfaces, although many lesions were found on the back and abdomen. The hands, feet, face, and neck were free. I found on my first examination, besides the lesions named, a number of dollar-sized infiltrated, red, scaly patches on the extremities and groups of pustules that had developed from the vesicles, patches of excoriation surrounded by vesicles or pustules, and here and there a group of small papules. The disease was worse in warm weather and itching was intense in all the lesions.

A careful examination of the patient failed to elicit anything that would give me a clew to the etiology of the disease. I found that very small quantities of any stimulant would make the trouble worse, and within a very short time. My patient used neither tobacco nor liquor. As he derived no benefit from several months' treatment, I suggested that he take an ocean voyage and while abroad to consult Kaposi. No diagnosis was made by Kaposi, but his treatment was about the same as had already been used, no benefit resulting. Mr. A—— went to England, where he consulted Malcom Morris, who pronounced the disease dermatitis herpetiformis and sent him to the arsenic springs in the south of France. No benefit was derived from the springs and he returned to me, and business calling him to Chicago I referred him to Dr. Hyde, who concurred in the diagnosis, and suggested a line of treatment which was followed for some time without any benefit. My patient married and his disease disappeared, and he has remained well ever since.

I have reported these cases as a text. It is now over a decade since Dr. Duhring first called attention to the disease under consideration, and, despite the fact that a few prominent dermatologists have refused to recognize it as an entity, the consensus of opinion of competent observers places it as a disease of the skin, in the totality of its symptoms entirely distinct from any other dermatological affection. It is true that in different attacks the lesions and their behavior may be the same as if occurring in some other disease of the skin, and, if they are watched but a short time, or are seen only in a single attack, there may be a liability of not recognizing the affection and placing it as an eczema, pemphigus, or erythema multiforme. The disease is not a very common one.

I have records of twelve cases, five of which have come under my care during the last two years. This is no evidence that the disease is becoming more frequent, but only that I am coming to recognize as dermatitis herpetiformis what earlier in my practice has been regarded as some other affection of the skin. With the exception of two of my cases (one of which was that of a paralytic, the other that of a sufferer with chorea), all of my patients were in apparent good health, and while some of the attacks lasted for months, and even longer, no effect was produced upon the general health other than would naturally result from the loss of sleep and the irritation of the intense pruritus, always present no matter what the lesion was. The disease is a dermatitis, and is manifested by multiform lesions, either in the same attack or in different attacks in the same individual. In one of my cases the first lesions were blebs and the disease was diagnosed and treated as pemphigus, and, it being seen in that stage only, it could not be recognized as anything else. Later, however, erythematous patches and small vesicles occurred, and it then had the appearance of an eczema, and the intense pruritus was favorable to such diagnosis.

A careful study of the lesions at this time showed a peculiarity in their behavior which is not found when they occur in other affections. It was noted that they came in crops, and that they were grouped. A crop of patches of vesicles or papules of the size of a pea to that of a ten-cent piece, covering an extremity or over the thorax or back, would appear during a night, the patches made up of three or more individual lesions. Later these gave place to crops of erythematous patches, the size of a pea to that of a dollar, which in turn were supplanted by vesicles or papules and sometimes by pustules. Severe pruritus was always present, no matter what the lesion was. It is easy to see how a single attack of the disease with a single anatomical lesion, such as a bleb or vesicle, might be mistaken for some other affection, but recurring attacks with different lesions should stamp the affection as dermatitis herpetiformis, if the lesions have the behavior stated.

The course of the individual lesions is acute, but that of the disease is chronic, and relapses are the rule. The etiology of the disease is obscure, but from the similarity of the symptoms and lesions to affections such as pemphigus, herpes zoster, and erythema multiforme, in which disturbance of the nervous system, either sensory, trophic, or vasomotor, seems to stand in a causal relation to the disease, we are led to the supposition that dermatitis herpetiformis should be traced to a similar origin. Corroborative symptoms, however, are found in only a few cases. In one of my cases paralysis has occurred, and one patient suffered from chorea, but the others failed to manifest by any symptom evidence pointing to any pathological condition of the nervous system that might stand as a cause of the outbreak. Dr. James McF. Winfield, in a paper read before the Pan-American Medical Congress, reported a series of four cases in which glycosuria was present, and he used this fact as an argument in favor of the nervous origin of the disease.

It is undoubtedly true that some cases trace their origin to pathological conditions of other organs than the nervous, and are cured permanently by the removal of these conditions.

Treatment.—A disease whose origin is so obscure is of necessity difficult of management, and I know of no line of internal or external medication that can be said to be fairly successful in all cases. Those cases that are due to a reflex will probably be cured by a line of medication directed to the removal of a gastric, hepatic, or renal disturbance that may exist. As the disease is essentially chronic, any line of treatment decided upon must be carried out persistently. In all cases particular attention must be given to hygienic conditions; the environment, habits, exercise, and diet must be regulated. Little is to be said re-

garding internal medication. A remedy that has been pretty extensively used is arsenic, and, as it is known to act favorably in the prevention of bleb formation in cases of pemphigus, we are led to think that in the disease under consideration in which the lesions were blebs or vesicles it might prove a valuable remedy. Whenever its use has been decided upon, it should be pushed to its full toleration and persisted in for a protracted period until it is positively shown that it is not influencing the disease favorably. Do not be too sanguine of benefit resulting from the use of arsenic, as it oftener fails than benefits. Iron, quinine, strychnine, and belladonna have all had advocates, but in my hands have not proved of much value. The valerianate of zinc in one-grain doses several times a day I have found of value in relieving the mental symptoms. Local treatment is of great importance. Pruritus is intense in every lesion, whether macule, papule, vesicle, bleb, or pustule, and calls loudly for relief. It has been my experience that no good results from the use of soothing applications, such as are of value in eczemas with similar lesions. Remedies that are harsh and irritating are of greater value, the object being to impress the nervous system profoundly, rather than to palliate the disease by soothing remedies. There will be times in the course of the affection when sedatives will be employed temporarily, but as curative agents they will be useless. Sulphur, ichthyol, and the preparations of tar I have found in the order named the best local applications. To get the best result from these remedies they must be rubbed over the surface thoroughly, not simply smeared over the eruption. The vesicles or blebs should be ruptured, either before the remedy is applied or by the friction used in its application.

Sulphur I use in ointment, ten to twenty-five per cent., and have it applied night and morning, or when the lesions are vesicular I use powdered sulphur in the morning and the ointment at night.

Ichthyol I use in lotion or ointment (ten to twenty-five per cent.), using the lotion several times during the day and applying the ointment at night. Resorcin, thymol, menthol, etc., I have also used, but from none of them have I had the good results that have followed the use of sulphur. What I said regarding persistence in the use of arsenic internally holds true in the use of a local remedy. No benefit results from the frequent change of remedies, either internal or external.

Baths, which are of so much value in pemphigus, I have found of little value in treating dermatitis herpetiformis, and use them only for purposes of cleanliness.

Disease of Basedow and Alopecia.—Dr. Berliner (Aix-la-Chapelle) reports, in the *Gazette hebdomadaire de Médecine et de Chirurgie*, a case of Basedow's disease, complicated with total alopecia. In spite of the cure of the exophthalmic goitre, entire baldness persisted. Dr. Rille (Vienna) observed a case of scleroderma with general alopecia. He thinks we shall have to admit, with Kaposi, that the two affections are the result of trophic troubles of central origin. Dr. Caspary (Königsberg) thinks that neurasthenia, nervous affections, and anæmia are rather the result than the cause of general alopecia. Dr. Galewsky (Dresden) has obtained favorable results by applications of chrysarobin. The hair that grew fell out a year later. The action of chrysarobin indicates, perhaps, the parasitic nature of general alopecia. Dr. Köbner (Berlin) thinks that, while some cases are of nervous origin, others are certainly parasitic. Dr. Kohn also reports a case of the disease of Basedow with general alopecia.

THE PATHOLOGY, DIAGNOSIS, AND TREATMENT OF ATROPHIC CATARRH.[1]

By JOHN NORTH, A.M., M.D., Ph.C., F.S.Sc. Lond.,

TOLEDO, OHIO,

PROFESSOR OF DISEASES OF THE NOSE, THROAT, AND LUNGS, AND CLINICAL RHINO-LARYNGOLOGY, TOLEDO MEDICAL COLLEGE; SURGEON IN CHARGE OF NOSE AND THROAT DEPARTMENT OF TOLEDO HOSPITAL; CONSULTANT TO ST. VINCENT HOSPITAL; PRESIDENT OF THE NORTHERN TRI-STATE MEDICAL ASSOCIATION.

"I pity the man who can travel from Dan to Bersheba, and cry, 'Tis all barren!'"—*Sterne.*

Various names have been given to the condition that we find in the diseases classed under the title of this paper. Among them we find atrophic rhinitis, atrophic catarrh, dry catarrh, ozæna, etc. The conditions we shall speak of are not diseases of themselves, but the result of diseases, some of them dating back to early childhood.

In science every effect is produced by a definite cause, the same cause operating under the same conditions always producing the same effect. In medicine we find a number of causes and forces, physical, chemical, microbic, and vital, operating to produce not a single effect but a combination of effects. When a number of these effects are grouped together and have been noticed in a number of individuals, either with or without a pathological lesion, it is called a disease. Some conditions which receive names and win their way into medical nosology often should not receive such a dignity, but should be regarded simply as conditions or sequences of an organ or apparatus of the body dependent upon previous diseases, of which they are only the results.

Sir Morell Mackenzie defines atrophic catarrh as follows: "Chronic inflammation of the lining membrane of the nose, in which this secretion, instead of flowing away, dries on the surface, giving rise to adherent brown or green flakes or crusty masses of dried mucus, which are apt to undergo decomposition and cause a disgusting and characteristic stench, known under the name of ozæna. There is often atrophy of the turbinated bodies and of the subjacent bony structure, while the nasal passages and meatuses are proportionately increased in capacity."

This definition is a good description of the conditions that exist, but it does not define them from the standpoint of pathology and pathological anatomy.

Pathology.—Pathology is understood by a large number of medical men as meaning simply the pathological anatomy or abnormal condition of an organ or tissue as seen through the microscope. If the microscopist detects no deviation from the normal in the tissue of the organ under examination, he jumps at the conclusion that it is healthy and in proper working order. The pathology of an organ or apparatus has reference to its abnormal function or action, from direct or remote causes operating upon and modifying or altering the normal or physiological function. Histology and pathological anatomy deal with the structure of the part, while physiology and pathology deal with the function of the part. Pathology bears the same relation to pathological anatomy that physiology does to histology. The two former deal with abnormal matter, while the two latter deal with normal matter. The views that I shall give you in regard to the etiology, pathology, and pathological anatomy of atrophic catarrh are very different from those you get from the text-books, but I think I can make my reasons for differing from recognized authority clear to every one. I use the term atrophic catarrh in its broadest sense, to include the various varieties.

Atrophic catarrh, instead of being a distinct disease, is the result of two previous diseases or conditions, or rather it is the third stage of a disease.

[1] Read before the Northern Tri-State Medical Association.

Atrophic catarrh never begins as atrophic catarrh. Atrophy is never the beginning. The three stages are as follows: First stage, that of purulent catarrh, usually of childhood. Second stage, hyperplastic catarrh, not hypertrophic catarrh. Third stage, atrophic catarrh.

We are very unfortunate in being compelled to use the word "catarrh" in speaking of diseased mucous membrane. Catarrh means flowing downward. Bosworth and others tell us that in "catarrh" we have a diminished rather than an increased flow of liquid. The word "rhinitis" is just as unfortunate, as it signifies inflammation, and we very seldom have true inflammation in catarrhal diseases. So we are compelled to use the word "catarrh" in referring to diseases of the nasal mucous membrane.

Purulent catarrh is about the only one of these diseases in which we have inflammation, and the only one in which the term "rhinitis" can be properly applied. In this, the first stage of the condition under consideration, we have a true catarrhal inflammation. In it we have all the cardinal principles of inflammation, including pus and microbes, with molecular death and destruction of tissues.

Emmett says we cannot have inflammation without molecular death.

Roswell Park, before the American Surgical Association, May 30, 1895, said: "Without infection no genuine inflammation: with infection inflammation, and, what always goes with conflagration, more or less destruction: congestion and exudation practically never lead to destruction: inflammation always does."

I think we cannot go far wrong in this matter if we accept the definition of inflammation proposed, for instance, by Metschnikoff, which is in effect as follows: "Inflammation generally must be regarded as a phagocytic reaction on the part of the organism against irritants. This reaction is carried out by the mobile phagocytes, sometimes alone, sometimes with the aid of the vascular phagocytes or of the nervous system. The irritants herein alluded to are of course micro-organisms. It is necessary to emphasize the fact that the essential phenomena of inflammation represent an actual struggle between the phagocytes and the irritant, or, as Virchow has aptly termed it, a "battle of the cells," and that pus and pus cells represent simply the débris, and are really the dead bodies of animal cells which have perished in the struggle."

Let us briefly refer to the structure of mucous membrane, as this is the part principally affected. Mucous membrane is described as comprised of three layers:

1st. A superficial layer, composed of epithelial cells.

2d. The mucosa proper, a layer composed of white fibrous and yellow connective elastic tissue embracing within their meshes blood-vessels, smooth muscular fibres, and different varieties of small glands, and presenting minute processes or villi. In this layer we have the mobile phagocytes.

3d. An internal layer of loose connective tissues, the submucous cellular tissues.

Purulent catarrh is more apt to occur in childhood than at any other period of life, yet it may occur at any time of life.

Now, what takes place in a case of purulent catarrh? First, we must have an irritant. This irritant consists of some form of pyogenic organism, some variety of the streptococcus or staphylococcus: the exact form that the disease assumes depends upon the variety of micro-organism present. This micro-organism finds lodgment upon the mucous membrane or within the follicles; then the mobile phagocytes come to the relief of the membrane and the battle commences, and as the result we have a large amount of débris thrown off, consisting of pus, dead epithelial cells, and mucous corpuscles. If the battle is allowed to progress, it results in the almost entire destruction of the epithelial layer of the membrane.

Beal and Tyson have shown that the mobile phagocytes of mucous membrane, in the healthy condition, become epithelial cells and take the place of the old worn-out epithelial cells. If the irritation is slight, they are modified and are thrown off as mucous corpuscles, but if the irritation is severe, and the battle rages long, they are aborted and are thrown off as pus cells. Nature in her efforts attempts to assist the phagocytes, throws out serum and lymph, which in time become organized and press upon the second layer of membrane, and then, after the battle is over, we have a condition of hyperplastic catarrh. The membrane becomes thickened and enlarged, but is denuded of its epithelium. This gives us the second stage or hyperplastic catarrh.

In hyperplastic catarrh we have a thickening of the membrane from the organization of the products of inflammation. New products are formed in the second layer of mucous membrane: these press upon and cause absorption of the membrane, interfering with its function; the secretions are modified, and we have a condition very different from that of hypertrophic catarrh, in which we have hypernutrition. As a result there is no increase of new tissue in the hyperplastic stage. There are simply over-nutrition and consequent overgrowth of existing elements dependent upon increased supply of nutrient pabulum.

In hyperplastic catarrh, with loss of the epithelial layer and pressure upon the follicles and other portions of the second layer, absorption and atrophy take place. After a longer or shorter length of time, the new hyperplastic material undergoes absorption, so that we have only a remnant of the nasal mucous membrane remaining. This gives atrophic catarrh. Hyperplastic catarrh is the result of purulent catarrh; the result of hyperplastic catarrh is atrophic catarrh. Atrophic catarrh is never the result of hypertrophic catarrh. Atrophic catarrh is a partial destruction of mucous membrane rather than atrophy. It is sometimes both combined.

I think that I have shown clearly that atrophic catarrh does not commence as atrophic catarrh, but is the result of hyperplasia, which is the result of purulent catarrh. If we trace back the history of any case of atrophic catarrh, we shall always find the history of the "snotty-nosed child." The period of purulent catarrh, when unaccompanied by proper treatment, lasts from five to twelve years. That of hyperplasia from eight to ten years before the atrophic stage sets in. I have never found a case of atrophic catarrh that I did not believe came from a case of purulent catarrh, through its hyperplastic stage. We may not always be able to trace their history through all the stages, yet it is a fact, notwithstanding, that the three stages must exist.

Diagnosis.—An anterior examination of the nostrils will reveal the presence of more or less greenish-yellow crusts. These crusts present an appearance which is absolutely characteristic of atrophic catarrh, differing from the crusts found in ulceration and necrosis, which are mingled with blood, unhealthy pus, and necrotic tissue. These crusts are formed from the evaporation of the water of the thin secretion from the atrophic membrane. If these crusts are not removed but are allowed to remain they become very thick, and sometimes fill up the entire nasal cavity. After remaining in contact with the membrane for some days, decomposition takes place between the crusts and membrance, which becomes very offensive. If the crusts are removed or come off, and the cavity is thoroughly cleaned, the odor ceases, while in ozæna from scrofula the discharge is always offensive; also in syphilitic ozæna. The mucous membrane is never

ulcerated in atrophic catarrh. The appearance of the nasal mucous membrane depends upon the length of time that the atrophic stage has existed. In the early period it is almost normal in appearance; in the latter periods its membrane presents almost a bloodless appearance and adheres closely to the bone. The bone sometimes appears shrunken and the nasal cavities appear large and roomy.

Treatment.—The first thing in treatment of atrophic catarrh is to clean the nasal cavities of all crusts and to see that they do not re-form. Without thorough cleanliness nothing can be done to cure atrophic catarrh.

There seems to be a prevailing opinion among physicians that atrophic catarrh cannot be cured; that all that can be done is to keep the nose free from crusts and give the patient temporary relief. Our books and teachers tell us that this is all that can be done.

After a number of years' experience in the treatment of atrophic catarrh I am prepared to say that not only can it be relieved but it can be cured in almost every case. It will take long and persistent daily treatment, extending over from one to three years. It is not necessary for the physician to make the treatment during all this time. With proper appliances the patient will be able to do most of the work, calling on the physician only once a week or once in two or three weeks. For the first few weeks the physician should make the treatments.

The crusts should not be removed by force. An atomizer should be used with an antiseptic and alkaline solution. Dobell's solution or some of its modifications can be used for this purpose. Seiler's tablets answer a good purpose, but I prefer the following:

℞ Resorcin	ʒ ss.
Sodium bicarbonate	gr. xv.
Sodium biborate	gr. xv.
Glycerin	ʒ i.
Aqueous extract of hamamelis	ʒ ij.
Water	enough to make half a pint.

This should be warmed and the nose thoroughly sprayed with it every day. I have a tablet made containing five grains of resorcin and two grains each of bicarbonate of sodium and biborate of sodium. One of these tablets is dissolved in one ounce of water, or, still better, in a saturated solution of hydronaphthol.

One of the foregoing solutions should be warmed and the nasal cavities thoroughly sprayed with it at least once every day. After the solution has been used thoroughly, the parts should be sprayed with warm vaseline containing ten drops of campho-menthol and five drops of eucalyptol to the ounce. This treatment should be persisted in till all the crusts come away and are prevented from re-forming. Then the patient is ready to commence active treatment. If the case is a mild one and not too far advanced, resorcin is one of the best applications to use. The resorcin wash should be used and then the nasal cavity thoroughly sprayed with vaseline and resorcin (one per cent.). As resorcin is insoluble in vaseline, it is first dissolved in hot glycerin and then mixed with the vaseline; in some cases thymol is also added in the proportion of five grains to the ounce. This treatment will clean the cavities thoroughly, act as a disinfectant, and promote the growth of healthy tissues. In old advanced cases, in which the membrane has atrophied to such an extent as to appear like parchment, with little or no secretion, I get better results with judicious use of trichloracetic acid.

I know of no remedy in the entire materia medica that is so useful in the treatment of all nose and throat troubles as trichloracetic acid. Dr. Stein, of Moscow, says that in solution of 1 to 500–2,000 it will keep all suppurative processes in abeyance for a week. In weak solutions it is one of the best antiseptic remedies that I ever employed, and it also causes stimulation to atrophic membrane to a greater extent than any other application with which I am acquainted.

Dr. Stein says: "Weak solutions of trichloracetic acid used in the nose in simple atrophic rhinitis for a considerable time sometimes produce such a decided hypertrophy of the turbinated membranes that it may become necessary to cauterize them in order to secure free breathing. No other medicine of which I am cognizant produces such a remarkable effect, and thus this agent is particularly applicable in the treatment of ozena. In true ozena I now apply stronger solutions than I did at first, *i.e.*, one-half to ten per cent. The odor is not so quickly nor so thoroughly abolished by any other medicinal agent as by the acid. Here it is certainly a specific."

From my use of trichloracetic acid during the past six years I agree with Dr. Stein in every particular. I keep a number of solutions of the acid on hand, varying from one to fifty per cent. After the nose is thoroughly cleansed with the resorcin solution, the part is dried with absorbent cotton, and then a two-per-cent. solution is applied on a probe with cotton to the diseased membrane: the strength is increased as the effect becomes less active, spraying afterward with the vaseline and resorcin.

We sometimes find a portion of the mucous membrane entirely denuded of epithelium and in which the glands are all destroyed, leaving a thin dry layer of membrane covering the bone. In these cases the treatment mentioned will not stimulate the part nor cause new epithelium to cover the atrophic part. In such cases it is necessary to stimulate the edges of the diseased part and cause the mobile leucocytes to collect at or near the edges. In time the entire surface becomes covered over with a thin mucous membrane, which after a further interval becomes thicker and furnishes sufficient moisture to prevent the formation of incrustations. In treatment of these cases I follow the method of the horticulturist when he finds a tree denuded of its bark, *i.e.*, blazing. Nature has made an effort to repair the injury by throwing out a secretion around the edges, which organizes and partially covers up the denuded surface by the formation of a thin bark. At this time the horticulturist scratches the edges of the thin bark and nature covers up still more of the surface. If this is continued, in time quite a large space will be covered up with this thin bark, and gradually it becomes thicker and almost removes the appearance of injury.

I proceed as follows: I clean the part thoroughly with the resorcin solution; then take a twenty-per-cent. solution of trichloracetic acid and apply to the edges of the atrophic space, not allowing it to come in contact with any other portion of the membrane. This produces slight irritation and causes the nutrient pabulum of the blood and also the mobile leucocytes to collect beneath the coagulated rind formed, and to become organized under its protection. The part should be well covered with solid vaseline and resorcin. If this treatment is followed up from time to time, the part, if not too large, will become completely covered, and the membrane be capable of performing at least a portion of its function. I have treated a number of cases by this method with good results.

321 Superior Street.

The Hands should be kept habitually clean. It is an extremely bad habit to "puddle in pus" perpetually. Of course, one cannot always avoid touching pus, but one can easily dress suppurating wounds or open small abscesses without getting infectious matter upon the fingers.—Ochsner.

Progress of Medical Science.

Intestinal Digestion.—The conditions which interfere with intestinal digestion are: 1. Those which arrest or delay the food in the stomach: (*a*) Mechanical stenosis of the pylorus; (*b*) motor insufficiency and dilatation. 2. Conditions affecting the gastric juice: (*a*) Achylia gastrica; (*b*) hyperchlorhydria. 3. Enteroptosis, causing obstruction at any one of the six main points of fixation. 4. Possible atrophy of the intestines. 5. Any condition which diminishes the amount of bile and of the pancreatic and intestinal juices normally found in the intestines.—Frank H. Murdoch, *American Medico-Surgical Bulletin*, November 28, 1896.

Indications for and against Operation in Cancer of the Uterus.—Dr. Emory Lanphear (*Medical Era*), from an experience of nearly one hundred hysterectomies for cancer of the uterus, reaches the following conclusions: "Radical operation is indicated: 1. As soon as a diagnosis of carcinoma of the cervix is made provided the disease is unquestionably not too far advanced for any possible benefit at the time of first examination. 2. Whenever there is a fungous growth upon the cervix (especially in a patient near the menopause), which persists in spite of treatment, even though there is no ulceration and but little tendency to spread. It is probably the papillary form of carcinoma cervicis (cauliflower cancer); and there is always involvement of the mucous membrane of the body, so that high amputation will not cure. 3. When there are one or more nodules in the mucous membrane of the cervix, which soon ulcerate and destroy the mucosa. Such trouble is almost invariably the nodular variety of carcinoma of the cervix. 4. When there is an infiltrate in or beneath the cervical mucous membrane, just within the os, which soon breaks down and destroys the cervix by erosion. It constitutes the variety known as cancer of the cervical mucous membrane ("eating cancer"), and may have progressed far before the os shows any marked change when viewed through the speculum. 5. When there is evidence of the existence of cancer of the parenchyma of the uterus (usually fibro-sarcoma), even if the cervix seems to be perfectly normal. Such cases are not rare. 6. Whenever at the menopause a glandular endometritis becomes inveterate, showing a tendency to degenerate into a typical malignant adenoma—that is, adeno-carcinoma (glandular carcinoma or primary cancer of the mucous membrane of the uterine body)—as indicated by (*a*) the appearance of irregular hemorrhages; (*b*) the presence of a serous, reddish, odorous discharge; and (*c*) paroxysmal pain. 7. In all cases in which there is even a strong suspicion of malignant disease. In early operation lies safety. I can quite agree with Pozzi that 'it may even happen that as a last resort against persistent hemorrhage alone, we are obliged to perform vaginal hysterectomy with only the diagnosis of probable cancer.' Operation is not indicated: 1. Whenever the disease is so far advanced that the uterus is fixed in the pelvis. 2. Whenever it is certain there is extensive cancerous infiltrate in the broad ligament. 3. Whenever the cancer involves the bladder. Implication of the posterior vaginal wall or even of the anterior part of the rectum is not necessarily a positive contraindication to operation. 4. When the 'cancerous cachexia' has become pronounced. 5. When the patient is too weak from repeated exhausting hemorrhages. 6. Whenever the diagnosis of sarcoma of the uterus is quite certain. In such cases there is always recurrence after removal, and the subjects die quickly. Palliative operation, such as curettage, burning with Paquelin cautery, etc., are indicated: 1. When there is marked sepsis, removal of the sloughing mass with the sharp curette, and the subsequent use of douches of solution of permanganate of potassium followed by insufflations of pyoktanin will greatly prolong life. 2. When there is excessive hemorrhage. In such cases curettage followed by cauterization and the after-treatment just mentioned will be of much benefit. 3. When pain is very severe. Even hysterectomy as a mere palliative measure is sometimes advisable, the pain being much less marked in recurring carcinoma in the pelvis.

Sterilization of Ligatures.—According to *Le Scalpel*, M. Saul proposes to the Medical Society of Berlin to sterilize catgut, which has not been disinfected by boiling water or by sublimate, by boiling alcohol. The boiling alcohol does not alter the product. He suggests that the catgut be boiled in the following mixture: Alcohol, eighty-five grams; water, ten grams; phenic acid, five grams. M. Tretrop proposes a simple process which can be applied to all ligatures, catgut silk, hair, and caoutchouc. Recognizing the necessity for absolute sterility, many surgeons reject the products of commerce and sterilize their own ligature and sutures. M. Tretrop has obtained excellent results with the following process. This method is advantageous, as it requires no apparatus, no heat, and no difficult manipulation. Turn five volumes of the formol of commerce, together with from forty to one hundred of formaldehyde, into one hundred volumes of distilled water. The threads to be sterilized are placed in a small flask in a glass which is completely filled with the solution until the mouth of the flask is immersed. He covers the mouth with a piece of filter paper moistened in a solution of formalin, 5 to 100. This cover protects against atmospheric particles. He keeps the flask at the temperature of the room. In his experience this varies from 12° to 18° C. It is to be noted that the rapidity of sterilization by means of formol increases with the temperature. After twenty-four hours he causes the solution to run off by inclining the flask at first and afterward raising the cork lightly. He watches carefully that his finger does not come in contact with the neck of the flask. He replaces the formol by ordinary alcohol, which dissolves the little formalin remaining in the sterilized threads. He removes the alcohol used for lavage as he did the formol, and replaces it by new alcohol. He covers the flask with filter paper again, and the materials thus prepared keep indefinitely. According to Vallmer, who first devised this use of formol, the absorption of the latter by catgut will not commence until after fifteen days.—*La Médecine Moderne*, March 14, 1896.

Gonorrhœal Rheumatism.—Dr. A. Dezanneau (*Le Scalpel*, October 4, 1896, p. 90) says that the habitual failure of internal medication in the treatment of gonorrhœal rheumatism is well known. The salicylate of sodium has no action; colchicum, veratrine, and alkalies in larger doses either do not act or act very feebly. Salol exerts a certain influence but irritates the kidneys. The iodides are liable to set up a urethritis, according to Balzer: moreover they produce gastric troubles and anæmia in certain patients. As to local treatment Dr. Dezanneau assures us that the new method of terebinthine baths give marked success. The technique is as follows: The terebinthine mixture employed by M. Balzer, who is the originator of this method, is:

℞ Watery emulsion of green soap.
Spirits of turpentine.....āā 100 grams.
Shake the mixture before using.

The terebinthine baths are employed in two forms—local and general. The latter is indicated in certain

cases of polyarthritis, when articulations are very far apart and when the position of the diseased joint makes the local bath inconvenient, as the shoulders, the hips, or the sterno-clavicular articulation. For this general bath one uses from one hundred and fifty to five hundred or even eight hundred grams, according to the susceptibility of the patient, as these baths produce sometimes a marked smarting. The bath should be used as warm as possible. The amount of the mixture and the temperature should be increased progressively as the patient becomes accustomed to them. The duration of the bath is from ten to twenty minutes. Sometimes the general bath causes a smarting of the skin and genital organs, which can be obviated by the application of vaseline. The local baths are employed when the diseased parts are near together and when the situation of the articulation favors it, as the knee, the elbow, etc. Local baths are better, because the strength of the solution and the temperature of the bath can be increased. Certain precautions should be observed in the giving of these baths: for example, one should not commence this treatment until after the disappearance of the acute phenomena, and the susceptibility of the patient should be tested before increasing progressively the quantity used. The turpentine bath has at the same time a revulsant and an absorbent action. The beneficial effects of the heat should not be overlooked. Surgical interference is not indicated except in purulent arthritis.

Kerosene Poisoning.—Dr. Johanessen reports a fatal case of poisoning from petroleum. He says that a distinction must be made according as to whether the petroleum vapor is inhaled, or the oil has been rubbed into the skin, or has been taken internally. It would appear, according to Lewin's researches, that among workers in petroleum no ill effect is produced—that is, as long as the vapor is inhaled in the open air; but in factories similar symptoms are produced as by ordinary gas. A feeling of exhilaration is first induced, then heaviness in the head, vertigo, loss of consciousness, or anæsthetic sleep. Cyanosis, contracted pupils, and vomiting may occur. Once a fatal result was seen. Chronic bronchitis with anæmia may appear after long exposure to the vapor. Results similar to the above have been obtained in animals. Hyperæmia, minute hemorrhages, a considerable hyperplasia of the pulmonary epithelium were among the chief morbid changes. Petroleum applied to the skin may induce moderately serious symptoms. A diffuse inflammation of the cutis may occur in severe cases. Petroleum has been taken internally with suicidal intention or by misadventure. The symptoms have not always been in proportion to the amount taken. There are two sets of symptoms: 1, Gastro-intestinal, the kidneys being also involved; and 2, nervous. In the former case there is vomiting as well as the local irritation in the mouth and gullet. Diarrhœa, with colic, may supervene. In the cerebral form there are headache, anxiety, vertigo, and the pulse is small and infrequent; collapse may occur. It resembles a medium degree of alcoholic poisoning. Tetanic convulsions have been seen. A marked petroleum smell has been noted in the sweat and also in the urine, which may sometimes smell of violets. The urine may also contain albumin and formed elements. In no previous case has an immediate fatal result been reported. The author refers to two recorded cases in children, both of whom recovered. The author's case occurred in a rachitic child who had suffered from diarrhœa. The amount taken was unknown. Vomiting ensued, and the stomach was washed out and clysters were used. Two hours afterward the child was unconscious, and three hours after admission into the hospital it died in coma. No pathological changes sufficient to account for death were found. The case appeared to be one of a cerebro-spinal intoxication. Frequent pulse, difficult breathing, and comparatively low temperature were observed.—*Berliner klinische Wochenschrift.*

The Circulation of the Blood in the Brain During the Epileptic Attack.—We learn from the *Occidental Medical Times* that Dr. A. Todorski has made a number of experiments on dogs in the laboratory of Professor Bechterew, in which he measured, during the epileptic attack, the arterial and venous blood pressure, as well as the cerebro-spinal pressure, which latter was taken in the foramen vertebrale from behind and above the arch of the atlas. The spasms were produced either by stimulation of the cerebral cortex, by means of the faradic current, or by venous injection of essence of absinthe. In cases in which the epileptiform spasms were produced by faradic stimulation of the cerebral cortex in dogs not under the influence of curare, an increase in the arterial presure, taken in the internal carotid or crural artery, set in some seconds after the stimulation or at its commencement; at the same time there was an elevation of the venous pressure (taken in the internal jugular and the longitudinal sinus). The venous pressure remains increased as long as the faradic current is applied. During the period of tonic spasms, a similar increase in the arterial and venous blood pressure is observed, reaching its maximum at the beginning of the clonic contractions. The arterial pressure diminishes before the venous blood pressure shows any diminution. The venous pressure again becomes normal at the end of the comatose state. The same observations were made on curarized dogs, and after section of the vagus and sympathetic, thus showing that the increase in the venous blood pressure in the brain was not due to obstruction to the flow of blood into the chest and abdominal cavities by the excessive muscular contractions. The increase in the pressure of the cerebro-spinal fluid during faradic stimulation runs parallel with the arterial and venous pressure. This increase lasts frequently longer than that of the arterial and venous pressure. The author concludes from these results that the rush of blood to the brain during the epileptic attack produces an increased secretion of cerebral lymph. When the epileptiform spasms were produced by injection of essence of absinthe, it was observed that the curve of increase of the cerebro-spinal pressure frequently showed an upward tendency immediately after the injection, while the arterial blood pressure fell. Whenever the increase in the cerebral pressure reached a certain height, the epileptic attack would set in, while the cerebro-spinal pressure would rise still higher. Otherwise, the results were the same as when stimulation was made with the faradic current.

Prevention of Mastoid Disease.—Dr. Burnett maintains that acute mastoiditis is an entirely unnecessary result of acute otitis media, and never occurs except as a consequence of improper treatment of the primary acute inflammation of the middle ear and the nasopharynx, usually inflamed at the same time. The treatment of an acute otitis, he claims, should be largely negative, especially after discharge sets in, as the result of either paracentesis or spontaneous rupture of the membrana tympani. This view is based on the fact that the acute otitis media is due to the presence of a pathogenic germ, generally the streptococcus, in the middle ear, whither it has gone from the nasopharynx. Inflation of the nasopharynx under such conditions tends not only to drive more such germs into the middle ear, but the germs already there into the mastoid cavity. Inflation of the nasopharynx also tends to force pathogenic germs into the

unaffected ear, if there be such, and set up inflammation there. To relieve carache in acute otitis media, a few drops, warmed, of a solution of carbolic acid (1 to 40) may be applied to the canal and membrana tympani, if it can be borne. Dry heat over and about the auricle, however, is often sufficient to give relief, and it never irritates. Leeching, counter-irritation, and all forms of anodyne drops are not only useless, but further irritate, cause artificial inflammation in the canal and membrana, and mask the true state of affairs. If pain in the ear continues and spontaneous rupture of the drum membrane does not occur in from six to twelve hours, paracentesis of the membrana tympani should be performed. This should be preceded by the instillation of a few drops of an antiseptic solution into the auditory canal. Immediately after paracentesis or spontaneous rupture of the membrana, nothing should be syringed, mopped, swabbed, or blown into the ear. The auditory meatus should be stopped with antiseptic gauze—preferably iodoform or carbolic-acid gauze—and let alone for twenty-four hours. The discharge which now sets in is beneficent and should be favored by the drainage obtained with the gauze, as just stated. If any other procedure is adopted, staphylococci, ever present on the skin of all of us, are likely to get into the auditory canal, upon the membrana, through the perforations, and into the middle ear and mastoid cavities. Secondary infection is thus set up, chronicity is established, and the physician in charge of the case is confronted with the direful sequelæ named above. The occurrence of acute mastoiditis as a sequel of acute otitis media has been especially frequent since the introduction of hydrogen binoxide into aural surgery. This can be explained by the expansive action of the drug named, which forces pus from the middle ear into the mastoid cavities.—*The American Journal of the Medical Sciences.*

Tuberculous Cervical Glands and Carious Teeth.—Dr. Starck was able to demonstrate, in forty-one per cent. of his cases of tuberculous cervical glands, the existence of carious teeth. The glandular disease corresponded in location, in time of development, and in intensity with the condition of the teeth. Caries of the teeth of one or the other side of the jaw was associated with enlargement of the glands of the same side, and caries of the front teeth existed in conjunction with enlargement of the anterior glands, while caries of the molars was combined with enlargement of the glands about the angle of the jaw. Previous to the development of the glandular enlargement, there was frequently a history of toothache or caries. Caries of many teeth was usually associated with enlargement of a chain of glands, while caries of a single tooth and slight enlargement of the glands existed together. He reports two cases in which he was able to demonstrate positively that carious teeth had been the point of entrance of the tuberculous poison. One was that of a boy, aged eighteen years, the other that of a girl, aged fourteen years. They had no hereditary predisposition to tuberculosis and previously had always been healthy. In both cases the glandular enlargement ensued subsequently to toothache. In the case of the boy, in two molar teeth numerous tubercle bacilli were demonstrated. In the case of the girl, between the roots of a molar tooth was seen a macroscopic suspicious granulation tissue, which, on microscopic examination, was found to consist of tuberculous nodules and giant cells. In this case, although operated upon, a recurrence ensued after an interval of a year and a quarter. In three other cases such intimate connection between caries of the teeth and tuberculosis of the teeth could not be proved, though it was probable. The carious glands and the enlarged glands should be removed at once, whereby the liability of general implication of the body is reduced to a minimum. A proper hygiene of the teeth is urged, to avoid the occurrence of such glanduar enlargements.—*Münchener medicinische Wochenschrift.*

Carcinoma of the Cervix Uteri in a Girl of Fourteen.—Dr. W. L. Little (*New Orleans Medical and Surgical Journal*, December, 1896) reports that he was called to see the patient in question, on May 15, 1895. She was anæmic, had but little appetite, and every month would complain of headache, backache, and general languor. He diagnosticated the case as one of chlorosis. After treatment, menstruation set in. Soon after this she suffered from menorrhagia and dysmenorrhœa, and subsequently had leucorrhœa. An examination was made, and cancer was suspected. After consultation this diagnosis was confirmed, but, because of extensive adhesions involving the cervix uteri, vaginal walls, and surrounding tissues, operation would have been futile. Later, the tissues began to break down from ulceration and the discharge became more characteristic, the rectal walls becoming implicated. These conditions became more aggravated, until the patient died, on October 23, 1896.

A Statistical Study of Epidemic Measles.—As a result of a careful study of epidemic measles, with especial consideration of the epidemic observed at Munich in the year 1887, Möller (*Archiv für Kinderheilkunde*, B. xxi., H. 4, p. 241) formulates the following conclusions: There is no such periodicity of epidemics of measles, with constant intervals, as to justify the acceptance of a law of periodicity. The occurrence of an epidemic of measles requires the introduction of the contagium and the presence of a number of persons not previously affected with the disease. Besides, the epidemic occurrence of measles depends upon the coincidence of yet unexplained accessory causes varying with the season of the year. Whether or not the warmer period of the year, directly through the higher temperature, or indirectly through attenuation of the contagium in consequence of freer ventilation of living rooms, exerts a favorable modifying influence upon the morbility of measles has not yet been determined. The mortality of measles in Munich has reached two maxima during the year for a period of twenty years, a smaller in December and a higher in May and June. The mortality of measles in Munich during the first and more especially during the second half of the decennium from 1880 to 1890, while almost treble the average for the preceding decennium, declined considerably in the succeeding years. No period of life possesses entire immunity from infection with measles, although the predisposition is less in infancy. Almost the total mortality in Munich is confined to the first five years of life; the first and second years present approximately the same absolute mortality. The relative mortality in Munich is for the first year fifty-five times, for the period from the second to the fifth year twelve times as high as that after the age of five years. Although in consequence of the shortening of the interval between epidemics the average age of morbility has fallen, a lowering of the average age of mortality has not taken place in Munich. Both sexes suffered alike in Munich in regard to the morbility of measles. The absolute as well as the relative mortality in Munich displayed considerable differences in different parts of the city. It rose and fell with the number of births. The explanation for the greater fatality in the suburban portions of the city populous with children is to be found in want of care and insufficient nutrition. Primary thoracic rachitis trebles the disposition of the patient suffering with measles to catarrhal pneumonia and doubles the gravity of this complication.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

New York, January 2, 1897.

PUBLIC MONEY FOR PRIVATE USES.

AT a recent dinner given by the Society of Medical Jurisprudence Mayor Strong made some very pertinent remarks on the private abuse of public charity in connection with the use of the city's money for the support of the many institutions that are constantly begging for special appropriations. He said very truly: "We should, as a municipality, cease to give city money to institutions that are organized to be carried on and supported by private subscription. We find in many instances that after three or four years these institutions come to the board of estimate and make claim to a share of the money set aside for the use of deserving institutions."

After asserting that the money thus obtained is seldom if ever used for the purposes indicated, he continued:

"The city is being preyed upon by a number of private institutions that, through the aid of the legislature, appear as claimants for some of the money devoted to charity and charitable work, and whose officers do not devote that money, when they get it, to the purpose of assisting the poor, as they assert they will apply it. It is you doctors and lawyers who can go before the board of estimate, and, by putting in a proper protest at the right time, can prevent these private institutions from getting public moneys that they use to pay off debt on real estate owned by them, or to increase their real-estate holdings, instead of giving it to the poor they profess to aid. They come and ask the board to award them sixty cents or fifty cents or thirty cents per head for the inmates in their institutions, and do not turn a cent of it over to the assistance of these inmates. The city should be compelled to abandon this system of aiding institutions organized with the specific pledge that they are to be supported by voluntary and private subscriptions."

All this is perfectly true, and it is encouraging to know that a high official acquainted with the internal workings of this gross abuse should thus emphatically call public attention to the matter. It is evidently the committee which can talk loudest and longest and which has the strongest pull with the commissioners that gets the best showing. The medical profession, at least, is sick of the cant about the deserving poor who can only be reached through special channels of discriminating charity. Nowadays discriminating charity, so-called, is a well-recognized plea for every form of covert swindling. The city's money is openly used for the promotion of private enterprises to advance designing doctors and hypocritical managers. Only last year a bill was rushed through the legislature to help support an institution having no claims whatever on charity and whose chief medical officer uses said institution in a most disgraceful manner as a means of advertising an absurd specialty. Other instances of this sort might be mentioned, but they are too well known to the profession to need special reference. If these fake enterprises are not self-supporting, they deserve a natural death. The poor have always been well cared for independently of this loud-mouthed and pretentious missionary work. There are too many hospitals already, while the dispensaries, public and private, exceed every necessity for which they were founded. In spite of all these facts the Board of Estimate has just granted the sum of one million and a half and over for the clamorous supplicants. If each one of the begging private charities, clinics, medical schools, and the like were compelled to present their special claims fairly and squarely before the public as a proper preliminary for obtaining necessary protests, much of this growing abuse might be effectually nipped in the bud.

THE DOCTOR'S MISTAKES.

WHILE it is unnecessary to deny that all human judgment is fallible, it is eminently judicious on the part of such as are called upon to venture opinions on probabilities to lessen as much as possible the chances of proving a rule. In the case of the doctor, the difficulty in fitting a prognosis to an ultimate fact is oftentimes insurmountable. The law of chances, with its multiplicity of controlling circumstances, is always against positive and unqualified assertions. The patient himself, with his hereditary proclivities, his individual environment, and his inherent vital power, is always an uncertain factor in a calculation of results. Even taking all such conditions into account, the best of men err. No one can be so sure that he is right that he has never had reason to regret that he has been too direct and too positive in the expression of an opinion. Our patients are never charitable in condoning this fault, but always hold it against the man who commits it. The more he attempts to explain, the worse off he is. The results of an autopsy are past all arguments for reconciling prognostications with facts. If the patient lives when otherwise he should die, he never loses his lucky privilege of talking back. His family and friends forget the joy of his recovery, often in spite of fate, in the satisfaction of getting even with the physician who gave up his patient so prematurely. The sympathies are always on the side of the man who wins, and, while no one regrets his reason for felicitation, the absence of one less witness against us might under other circumstances be borne by us with becoming resignation. The lesson is learned too late, that of saying and promising too much, and in thus doing more than our real duty to our patients. When we

cannot control the causes of disaster, it is worse than folly to predict results. If we mistake a seventy-year clock for a twenty-year one, the pendulum in the former generally swings on until it runs down in its own regular way. It is the vital pendulum, after all, that must be studied, and until it actually stops it is never safe to say what is or what will be.

In all our relations with our patients, it is the safer and better rule to be more than cautious in our temptations to think aloud in their presence. A discrete general guards his line of possible retreat with as much care as that of attack, concluding that while it is quite bad enough to be defeated, it is still worse to be hopelessly bagged by the enemy. The older practitioner need not be told that the practice of his art is constantly beset by startling surprises. Patients not only get well who should die, but many die without ostensible scientific reasons. To reconcile these constantly recurring experiences makes him an ever-ready trimmer to circumstances and an adept diplomatist with shifting fortune. While apparently knowing everything, he finds it eminently fitting his actual position to know little and say less. The loophole of expediency is as essential to him as are his advice and prescription to his patient. He learns to be astonished at nothing and always on the lookout for the unexpected. A sudden death is always explained with greater plausibility by the man who never declares his positive prognosis than by the one who has previously committed himself to its impossibility. So also with a doubtful diagnosis. It is always wiser to wait and see the eruption than on general reasoning to promise its appearance, to be sure that pus is present before risking a dry tap. The qualifying "if" comes in everywhere and every time. If the patient does not die, he may live; if pus is not present, the signs are simply misleading; if the case is not one of measles, the clinical history is wrong and the patient has not been exposed; if it is not diphtheria, the bacteriological examination is at fault; if the wound does not heal, the sutures were not thoroughly aseptic. When nothing is promised, nothing is expected. We must balance one condition by the other, and the more evenly we do this the less often will the physician be charged with what he cannot reasonably help. A guarded mouth never needs to explain why the foot dropped in.

YAWS.

Most readers probably have an indefinite idea as to what constitutes the disease termed "yaws." They know the term as a synonym of frambœsia, and are aware that the latter name is derived from the resemblance which the fungus-like outgrowths or vegetations bear to the raspberry. Recent graduates can tell you offhand that it is a contagious disease of chronic course, occurring in India, the West Indies, and upon the west coast of Africa, where it exists in endemic form; but do not ask them to go into the etiology. Indeed, unless the student has come from one of these far-off lands himself, he will scarcely be able to give a good description of the affection or shed light upon its behavior with or without drug administration. It is therefore with considerable satisfaction that we see the term "yaws" at the head of an article bearing the name of Sir Jonathan Hutchinson, in *The Medical Press and Circular* of November 18, 1896. The writer here expressed the conviction that there is no such disease as yaws, and he asserts that he has long been of the opinion that the latter is simply syphilis modified by climate and race.

The term frambœsia, he recalls, was applied to outbreaks of syphilis in Scotland many years ago, when the eruptions were associated with papillary overgrowth giving the appearances which were thought to resemble raspberries. Frambœsia-like eruptions are met with in syphilitic subjects at the present time in England, and lesions of a granulomatous nature are not uncommon in European syphilitics.

If a negro with yaws starts across the Atlantic, his disease develops into unmistakable syphilis before he has been long on his voyage. This is the reason that cases do not arrive in England to become the subject of scientific investigation. While not admitting the identity of the disease with syphilis, many physicians in countries where it flourishes admit the efficacy of mercury. Reinfection is admitted for yaws, but the same is true of syphilis, and in the literature of the subject the distinguished author finds no differential feature which clearly points to the disease in question not being syphilis.

News of the Week.

The Charing Cross Hospital in London is said to be in financial straits, and the hospital authorities have made a modest appeal to the charitable public for half a million dollars to get them out of their distress.

A Medical Report Without the Sanction of the Medical Staff.—We have received a document signed by the entire consulting medical staff of the Hebrew Sheltering Guardian Orphan Asylum, viz., Carl Beck, M.D., W. T. Alexander, M.D., Henry S. Oppenheimer, M.D., James G. Wallach, M.D., H. T. Brooks, M.D., George H. Fox, M.D., A. T. Swan, M.D., William S. Gottheil, M.D., stating that the medical report in the recently issued annual report of the said asylum was made without the knowledge or consent of the medical officers of the institution (!). The consulting medical board desires to disclaim all responsibility therefor. Who then is capable of bearing the responsibility? The doctor is growing to be a useless appendage even to a hospital!

Christmas in the Hospitals.—The Polyclinic Hospital was destroyed by fire, which spread from a burning factory in the rear, on Christmas morning. There were fifty-five patients in the building at the time, but all were removed in safety to a neighboring hotel. Two bodies of patients recently dead were also removed without accident. In the afternoon of the same day there was a small fire in St. John's Guild Free Hospital for Children in West Sixty-first Street.

It was extinguished by means of a few pailfuls of water and very little damage was done. There were more than thirty patients in the building, but it was not found necessary to remove them. A small fire in some old clothes in a closet in the Brooklyn Orphan Asylum on Christmas evening did no damage beyond scorching the woodwork of the closet, but it created intense excitement for a while among the children.

The Plague in London.—There have been two cases of the bubonic plague in London, occurring in the persons of two sailors recently arrived from Bombay. The cases occurred in September and October, and no others have been discovered since that time.

International Medical Congress.—The managers of the surgical section of the Twelfth International Medical Congress to be held in Moscow, Russia, in August, 1897, have invited Dr. Stephen Smith to accept an honorary presidency and preside at one session of the section.

The Albany Medical College Alumni Association of Greater New York.—At the annual meeting of the above-mentioned association held at the residence of the president, Dr. John W. Warner, No. 107 West Seventy-second Street, New York, on December 17, 1896, the following officers were elected for the ensuing year: *President*, William H. Thomson; *Vice-President*, Reuben B. Burton; *Secretary*, Warren C. Spalding; *Assistant Secretary*, Henry T. Brooks; *Treasurer*, Edward F. Quinlan. The annual banquet will be held Thursday, January 21, 1897.

Prohibition Whiskey.—At the Benwood oil field in Monroe County, O., four men have been killed and a dozen others poisoned by a substitute for spirits said to be composed of alcohol, cinnamon, and sugar. It was supposed to be diluted with water before being taken. The liquid was sold by a local grocer, and does not seem to have been put up in conformity to the pure-food law.

Philadelphia County Medical Society.—At a stated meeting of the Philadelphia County Medical Society, held on December 23d, Dr. Silas D. Updegrove read a communication entitled "A Uniform Standard of Medical Education for the Degree of Doctor of Medicine." Dr. F. Savary Pearce read a paper entitled "The Protean Influence of Pregnancy upon Idiopathic Epilepsy." Dr. Mordecai Price read a paper entitled "A Report of Cases in Abdominal Surgery, with Remarks."

Execution by Gas.—Some time ago the Allegheny County (Pa.) Medical Society appointed a committee to make an exhaustive investigation of the present methods of executing condemned criminals, and to recommend a substitute for hanging or killing by electricity. The committee has now concluded its investigations, and will recommend that gas be substituted for the rope and electric chair. It is claimed that condemned prisoners could be put to death by this agent painlessly during sleep. It is proposed that the society draft a bill for presentation to the Pennsylvania legislature this winter providing for the change.

More Resignations from the Staff of the "Medico-Surgical Bulletin."—The following are the additional resignations from the editorial staff of the *American Medico-Surgical Bulletin:* Drs. William H. Porter, William C. Guth, Thomas S. Southworth, Adolph Zeh, T. Halsted Myers, John Hoch, and Adolph Barron.

The Plague at Bombay is increasing. An Associated Press dispatch, dated December 28th, states that there have been 2,094 cases and 1,494 deaths from that cause up to date. The exodus from the city continues, and the newspapers threaten the natives with martial law unless they conform with the sanitary regulations.

A Medal in Commemoration of Dr. Muhlenberg, the founder of St. Luke's Hospital in this city, was presented on December 28th to the board of managers by the American Numismatic and Archæological Society.

Trouble in a Hospital.—The physicians and nurses of the New York Medical College and Hospital for Women have had a disagreement with the trustees and have severed their connection with the institution. The hospital belongs to the homœopathic school.

The New York Polyclinic Hospital, which was burned on Christmas morning, is to have a new site and a new building as soon as the necessary funds can be obtained. For the present the trustees will secure temporary quarters as near as possible to the site of the former building.

Death of a Bone Setter.—"Dr." Charles Sweet, who at one time enjoyed a great reputation throughout New England as a natural bone setter, died at his home in Lebanon, Conn., on December 22d, at the age of eighty-five years. His cures, which were effected chiefly by the forcible breaking up of adhesions in cases of fibrous ankylosis following fracture, won him fame and considerable money. All the members of his family were "gifted" in the same way as himself.

Mrs. Garrett Anderson, M.D., has been elected president of the East Anglian branch of the British Medical Association, much to the disgust of some of the misogynists of the profession in England.

Navy Department, Bureau of Medicine and Surgery, Washington, D. C. Changes in the medical corps of the United States navy for the week ending December 26, 1896. December 21st.—Passed Assistant Surgeon R. M. Kennedy, ordered to the Naval Hospital, Norfolk, December 28th. December 22d.—Surgeon Charles T. Hibbett ordered to the Norfolk navy yard. Surgeon N. McP. Ferebee detached from the Norfolk navy yard and ordered to hold himself in readiness for sea. December 23d.—Surgeon R. Whiting detached from the *St. Mary's* and ordered before the retiring board at Washington, December 28th, then placed on waiting orders. December 24th.—Passed Assistant Surgeon R. P. Crandall detached from the Naval Hospital, New York, and ordered to the *St. Mary's*.

The County Medical Society on Leprosy.—At the regular meeting of the Medical Society of the County of New York, held December 28th, the committee on leprosy, consisting of Drs. George B. Fowler, Fox, Piffard, and A. A. Smith, presented its report. The substance of the report was that, while leprosy may undoubtedly, under certain circumstances, be communicated by contact, yet the disease is not dangerously contagious, and that the adoption of a policy of segregation here would be unnecessary and unjustifiable.

Succi, the Faster, recently gave a fasting exhibition in Paris, at the conclusion of which he became insane and was taken to a hospital. He was born in Italy about forty years ago, and during the past ten years had given fasting exhibitions for a living and was said to have made a moderate fortune in that way. In 1890 he gave a six weeks' fasting exhibition at a vaudeville house in this city. His claim was that he had discovered, while travelling in Africa, a plant the juice of which had the property of retarding tissue changes, so that it was possible to exist and maintain one's strength for a long time without food by taking a small quantity of this juice, which he called his "elixir," from time to time.

Pasteur's Final Entombment took place in Paris on Saturday morning, December 26th. It was intended to have the ceremony take place on December 27th, the anniversary of his birth, but as that day was Sunday it was decided that it should be on the day preceding.

Poisoned by Headcheese.—Twenty-five men of the cavalry detachment stationed at West Point were made seriously ill by some canned headcheese which was served to them at supper on December 21st.

Influenza is reported to be more prevalent in Berlin at present than for two or three years past.

Typhoid Fever at Mount Sinai Training School.—There have been recently twelve cases of typhoid fever among the sixty-six pupils in the training school for nurses connected with the Mount Sinai Hospital in this city. It is not known how the disease was acquired.

Medical Inspection of Schools.—Dr. George B. Fowler writes: "In your notice of the medical inspection of schools on page 931 of your last issue, you erroneously state that the appropriation was granted to the board of education. The fact is that the whole scheme originated with the board of health and the appropriation was granted to it. The process is being carried out by said board, and the co-operation of the board of education was sought and, after considerable explanation, was granted."

The Pan-American Medical Congress.—A curious boycott seems to have been placed upon the Mexican meeting by the medical press of this country. We have seen no report of the meeting in any of our esteemed contemporaries, save a letter in the *Medical News*, copied by the *Columbus Medical Journal*, in which two or three slight inaccuracies in our own account, due to the unavoidable haste of preparing a telegraphic report, were faithfully reproduced. We cannot understand this universal silence, but we think our contemporaries have been somewhat discourteous toward our Mexican confrères, as well as neglectful of the small number among their readers who have not the privilege of keeping up with the times by gleaning the weekly budget of news always found in the MEDICAL RECORD.

Preserved Meat in France.—After January 1, 1897, the stock of preserved meat for consumption in the French army can only be replenished with meat preserved in France or the colonies, or in countries under her protection, such meat to be furnished by native cattle, and the preserving to take place under the supervision of the State or in a State establishment.—*Médecine Moderne.*

The Hughlings Jackson Lecture.—The Neurological Society of London has voted to institute an annual lecture bearing the name of the first president of the society. Unlike most annual lectures established to perpetuate the memory of some great man or benefactor, this will be begun in the lifetime of the one to be commemorated, and the first lecture will be delivered by Dr. Hughlings Jackson himself.

Wisconsin State Hospital for the Insane.—Dr. Alfred W. Wilmarth, first assistant physician in the Pennsylvania State Hospital for the Insane at Norristown, has been elected superintendent of the Wisconsin State Hospital for the Insane at Chippewa Falls. Dr. Wilmarth was formerly assistant superintendent of the Pennsylvania Institution for Feeble-Minded Children, at Elwyn.

Philadelphia Pediatric Society.—The Philadelphia Pediatric Society was organized at a largely attended meeting held in the hall of the College of Physicians on December 22d. Constitution and bylaws were adopted, and the following officers elected for the ensuing year: *President*, Dr. J. P. Crozer Griffith; *First Vice-President*, Dr. E. Graham; *Second Vice-President*, Dr. Arthur V. Meigs; *Third Vice-President*, Dr. F. A. Packard; *Secretary*, Dr. Alfred Hand, Jr.; *Treasurer*, Dr. C. F. Pettibone; *Executive Committee*, Drs. Alfred Stengel, J. Madison Taylor, Charles W. Burr, William B. Atkinson, and Thompson S. Westcott.

"Science Made in Germany."—In my last letter I referred to the fact that a German ophthalmic surgeon had been called to examine Queen Victoria's eyesight. We have now had another example of "science made in Germany." The justly celebrated Dr. Koch has just sailed from here for the Cape to investigate, at the instigation of the Cape government, the rinderpest, which is now devastating South Africa. With all due respect to the Berlin savant, surely the methods of investigation are now such common property, and there are among us so many well-known pathologists, that it would have been possible to find many who were quite as capable of undertaking such an inquiry.—*London Correspondence of the Therapeutic Gazette.*

The Associated Alumni of the Mount Sinai Hospital, newly organized, have elected the following officers: *President*, Dr. Albert H. Fridenberg; *Vice-President*, Dr. Richard H. Cunningham; *Secretary*, Dr. Martin W. Ware; *Treasurer*, Dr. Edwin Hernberger.

Medical Inspectors for Public Schools.—The Philadelphia board of education has elected Dr. Katherine Kollock assistant professor of physiology and hygiene in the Girls' High School. Her duties will include the medical supervision of the pupils attending the school. In commending this action of the board of education, Dr. William H. Ford, president of the board of health, expressed the hope that in time similar supervision will be extended to every school in the city.

A Duellist Doctor.—That it is not always well for a physician to enjoy a reputation for duelling was illustrated last week in the upper part of the city. The report goes that a graduate of a German university, whose face bears the scars of many a *mensur*, had recounted his exploits and prowess to a druggist's clerk with whom he had a personal difference of opinion. It is even stated that a threat had been made to add the aforesaid dispenser of drugs and toilet articles to the already long list of victims whose blood had tinged the waters of the Necker and the Rhine. It was therefore not so much to be wondered at that, when awakened in the dead of night by a pounding on the drugstore door, accompanied by sundry deep-toned shouts, the clerk should have become terror-stricken on catching sight of his most dreaded foe through the window pane. He rushed to the telephone and a hurry call was sent in to the nearest police station for a squad to arrest a would-be murderer. It required but a few minutes for a detachment of bluecoats to reach the scene, when it was learned that a desire to save life and not kill had actuated the physician in his efforts to gain entrance to the pharmacy. A certain drug was needed for a dying woman in the vicinity. The police remained while the drug clerk put it up. The patient recovered and the doctor laughed last.

College of Physicians of Philadelphia.—At a stated meeting of the section on general surgery of the College of Physicians of Philadelphia, Dr. Randolph Faries reported a case of indirect inguinal hernia in a child two weeks old. Dr. Thomas S. K. Morton exhibited a case of cured dermoid cyst of the orbit. Dr. Max J. Stern exhibited for Dr. John B. Roberts photographs and a skiagraph of a case of Charcot's disease of the knee. Dr. Thomas G. Morton exhibited a case of locomotor ataxia presenting an arthropathy at the right knee, the patella being displaced to the outer aspect of the joint. The condyles of the femur were apparently enlarged and the calf of the leg was also of unusual size. Dr. Stern reported a case of osteotomy for deformity following fracture of the lower end of the radius, and exhibited skiagraphs, photographs, and a plaster cast. Dr. A. C. Wood read for Dr. C. B. Penrose the report of a case of pancreatic cyst cured by operation. Dr. W. W. Keen reported a case of a large pancreatic cyst, abdominal section and drainage, recovery. A dinner, given by the college on December 15th, was largely attended. The special feature of the occasion was the presentation of a bust of Dr. Henry J. Bigelow by Dr. John B. Roberts in behalf of a son of Dr. Bigelow. The gift was gracefully accepted by the president of the college, Dr. J. M. Da Costa. Toasts were responded to by Drs. S. Weir Mitchell, who made a humorous narration in verse: Dr. William Osler, of Baltimore; Drs. Horatio C. Wood, William W. Keen, and George E. de Schweinitz. Extemporaneous remarks were made by Drs. Abraham Jacobi and John S. Billings, of New York, and Dr. Robert Fletcher, of Washington, D. C. At a stated meeting of the section on gynecology on December 18th Dr. Alexander J. C. Skene, of Brooklyn, read a paper entitled "Notes on the Diagnosis and Treatment of Diseases of the Female Urinary Organs." Following the address a well-attended reception was held at the University Club.

Obituary Notes.—Dr. Charles Heitzmann, one of the best-known pathologists and dermatologists of this country, died in Rome, Italy, on December 6, 1896, of chronic myocarditis.—Dr. James H. Trumbull, of Chili, died in Iquique on November 12th. He was born in New England and was graduated from Yale College in the class of '48. He studied medicine in the College of Physicians and Surgeons in this city and went to Chili immediately after graduation in 1852. He had resided in that country since then, being one of the leaders in the profession in Chili.—Dr. Selden W. Jones, of Leavenworth, Kan., one of the oldest practising physicians in the State, died on December 16th. He was a native of Boston, Mass.—Dr. Frederick Arnold Manning died on December 3d, in Denver. He was born in Eddyville, Ia., May 4, 1859, and was graduated in medicine at the College of Physicians and Surgeons, New York. He served for eighteen months on the surgical house staff of the New York Hospital. He then entered practice in this city and was appointed to various hospitals in positions of trust. In the summer of 1894 he was attacked by pulmonary tuberculosis and in 1895 he went to Colorado in search of health. The form of his disease was, however, active from the start and the climatic advantages were unable to check its progress. Dr. Manning was a brave, kind-hearted, unselfish man, and will be sincerely mourned by all who knew him. He was a member of the leading medical societies of this city. He leaves a wife and child. He was buried at South Coventry, Conn.—Dr. George Urquhart died at Wilkesbarre on December 19th at the age of sixty-eight years. He was graduated from Jefferson Medical College in 1850, and was among the first physicians to volunteer to go to Gettysburg to care for the wounded after the great battle.—Dr. J. W. Cole, of Hazelton, died on December 15th of pneumonia at the age of thirty-five years.—Dr. James Robinson died at Philadelphia on December 13th, at the age of fifty-one years. He was born in Ireland, and graduated from Jefferson Medical College in 1887. He had been for a number of years a pastor in the Presbyterian Church.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON OBSTETRICS AND GYNECOLOGY.

Special Meeting, November 27, 1896.

R. W. PRYOR, M.D., CHAIRMAN.

The Treatment of Puerperal Eclampsia.—DR. J. CLIFTON EDGAR read the paper (see p. 913, vol. 50),

Eclampsia Can be Prevented.—DR. EDWARD P. DAVIS, of Philadelphia, opened the discussion. Two years ago he had spoken in New York on the toxæmia of pregnancy, and he might say that experience since had strengthened his belief that eclampsia was largely preventable. The amount of urine was, as a rule, a valuable index to the amount of solids, a scant quantity pointing to deficient excretion and the necessity for special diet or preventive measures. Tarnier's statement that the mortality at his clinic had been thirty-eight per cent. until he had adopted in all cases of deficient elimination a rigid milk diet, when it fell to nine per cent., was a most forcible illustration of the value of preventive treatment.

Dr. Davis called attention to the fact that symptoms relating to the nervous system, as melancholia, were frequently the first indications of deficient elimination. The warm bath at night took the place of chloral or bromides in inducing sleep and at the same time aided elimination. It was well to give every pregnant woman a diet list.

The interruption of pregnancy when the pre-eclamptic condition was present, in the light of modern science, was not debatable. It was the imperative duty of the obstetrician. He had found dilatation more equal and complete under dilating-bags than when the hands alone were used.

Before speaking of the treatment of the eclamptic attack, he wished to say that those who followed out the idea of a toxæmic cause would have few cases among their own patients. But there were consultation cases in which eclampsia had already developed. Certainly emptying the uterus was important. Controlling the convulsions was immediately indicated. Cæsarean section would be the ideal method of emptying the uterus at once if the child were the chief consideration, but it was likely to be dead when the obstetrician was called, or stood but little chance of living afterward. Consequently the life of the mother was first to be considered, and if a surgical operation were required it was better to make a clean Dührssen incision into the neck of the womb.

Regarding veratrum viride, he agreed with the author that it belonged to the apoplectiform cases alone. Salines were indicated. Atropine was to be used in pulmonary œdema. Digitalis and strychnine gave better results than the latter drug alone. On other points the author agreed with Dr. Edgar. Since it had become his custom to have the elimination of pregnant women watched, he had not seen a case of eclampsia except in consultation practice.

Empty the Uterus Too Soon Rather than Too Late.—DR. CHARLES JEWETT, of Brooklyn, believed in prophylactic measures, remedial and dietetic, when the urine and other facts pointed to deficient elimination and threatening eclampsia, but when these measures failed to produce a response he emptied the uterus, and preferred to empty it too early rather than take the chances involved in allowing the symptoms to go on. The viability of the child was worth little prior to the ninth month, in the uræmic mother. For dilatation the water bag was, all things considered, worth more than the hand, but there were cases which yielded so readily to the hand that it constituted the more rapid and satisfactory means. For the control of eclampsia in labor, chloroform was very valuable, but it added danger if its use had to be continued long. Veratrum viride was the most valuable of the drugs. Dührssen's incisions should be reserved for emergency. He believed venesection would come into more general favor, especially when the attack was attended by a good deal of cyanosis. Saline injections had been of great value in his hands. He had relied largely on water as a diuretic in prophylactic treatment. While milk diet was of value, yet in his experience it had not been sufficient without other food to support the patient more than two weeks. His experience had not been so favorable with trinitroglycerin as with veratrum.

Surgical Methods in Obstetrics.—DR. EGBERT H. GRANDIN thought there was little ground for difference of opinion with regard to the prophylactic treatment of eclampsia. He was satisfied that Dr. Davis did not make use of too strong a statement when he said that eclampsia was a preventable disease. A pregnant woman duly watched by her attendant ought not to have eclampsia, or, if premonitory symptoms developed, she ought not to die. In the past we had been taught too much to watch for albumin and too little to watch for urea. Toxæmia and not albuminuria was the term which should be employed. The term urinæmia and not eclampsia should be drilled into the mind of the student.

The speaker said he now came to the question which interested him most, and yet he approached it with diffidence, since quite lately in this city a leader in the obstetrical world had referred rather sneeringly to the surgical tendency of the younger obstetricians. It was the surgical tendencies, together with the aseptic tendencies, which had made the lying-in room to-day as different from that of the past as the heavens were above the earth. It was the distinctly surgical tendencies of the younger gynecologists and obstetricians which were robbing labor of its dangers. As he stood prepared again to advocate the surgical tendencies, it was with the diffidence which the pupil should always yield to the master.

The following statements were based on his personal experience: Given a woman with impending eclampsia, and the rule of action should be surgical as speedily as the surgical instrument which the Almighty had given us, the best of all, the hand, could do it. There was no time for Barnes' bags, nor for other dilating-bags. After the seventh month and a half of utero-gestation, in primiparæ as well as in multiparæ, the hand, and the hand alone, barring exceptional cases, could, in a shorter time than any drug could possibly do, place the woman in such a position that the mortality rate, as pointed out by Dr. Edgar, was reduced to seven per cent. He was, however, in full accord with all that the reader had said in deprecation of the irrational use of the hand. He also objected to the use of that old and abominable term, *accouchement forcé*, which apparently had been the cause at the late Geneva conference of scarcely a voice being raised in favor of rapidly emptying the uterus. The procedure which he advocated, and which had been described by Dr. Edgar, was not *accouchement forcé*. There was nothing forcible about it. It was simply a muscle yielding to applied pressure. The uterine muscle would yield to the applied pressure of finger after finger even as would the sphincter ani, only it took a little longer. When time was not a factor, the gauze tamponade should always be used for six or eight hours to secure preliminary softening of the cervix and lower uterine segment. In every case in which urgency did not allow of this preliminary tam-

ponade, any man who could not dilate the cervix and empty it within thirty minutes, in ninety-eight and a half per cent. of cases, did not know how. And absolutely no force should be used at all. Due care should be taken entirely to paralyze the cervix and lower uterine segment before any attempt was made to extract the child, which should always be done by version when there was sufficient liquor amnii present to allow it. Delivery must be effected rapidly, else the cervix would recontract. Then the colon should be washed out with gallons of water, as much as sixteen to twenty gallons. This would also cause a more profuse diuresis than a Turkish bath. With such treatment one would find even the mortality of seven per cent. in eclampsia disappearing. He was opposed to Cæsarean section, and had made deep incisions into the cervix but once. He believed in the use of drugs after the uterus had been emptied, but he did not believe in waiting before this for their slow action, when the uterus could be emptied within thirty minutes by the hand and the eclamptic seizures reduced thereby to one-sixth in frequency. If one was not afraid of the surgical tendency in obstetrics and would leave ruts, he would rarely lose a woman in eclampsia, and he might save a third of the children.

Dr. Lusk's Reply.—Dr. William T. Lusk was the next speaker. In reply to his interrogatory, he was informed by Dr. Grandin that it was to a stenographer's report of some remarks which he had made that Dr. Grandin had referred. Dr. Lusk then said he presumed that nobody had been more consistent than he had been from the time of his first essay at teaching, in maintaining that the proper treatment of eclampsia was, whenever the symptoms were sufficiently threatening, or whenever they were threatening at all during pregnancy or labor, to empty the uterus. He was glad to learn that the younger men were keen in mind in that respect. But surgical evacuation of the uterus, or call it by any other name, was abortion, and we did not want to practise abortion unless we had reason for doing so. We did not want to empty the uterus unless there were some symptoms. He presumed Dr. Grandin would agree with him on that point. Yet within twelve months a woman had been brought to him for consultation as to emptying the uterus when there was not a single symptom, but only a trace of albumin in the urine. All knew that during the second half of pregnancy a large proportion of normal women had a slight trace of albumin in the urine. This called, perhaps, for watchfulness and diuretic treatment, but it did not call for surgical treatment.

With regard to prophylaxis, one of the speakers had said, and correctly said, that it was not alone the albumin which should be considered, but all the constituents of the urine. But mention was made of a fall in the amount of urea, while the fact was ignored that urea was not poisonous at all, and the amount of urine was not considered. In some older works on physiology four hundred grains were laid down as an average amount of urea passed daily, yet a woman had been brought to him for consultation as to emptying the uterus because she was passing only two hundred grains of urea a day. The amount of urine was from fifty-two to sixty ounces, and there was not a single symptom. The family was anxious, but he advised waiting, and said that if she reached the thirty-sixth week he would not care if labor was induced. His advice to try milk diet was followed, and immediately the urea increased from two hundred to four hundred grains a day, allowing that the percentage in the urine was the same. She went to term and bore a healthy baby. The course pursued in this case was what he meant in contrast to surgical tendencies. If that woman had had any puffiness of the eyes, dizziness, headache, symptoms of poisoning, he presumed he would have been as ready to empty the uterus as Dr. Grandin would be. But he did not consider emptying the uterus so innocent a thing, in spite of the surgical skill of the younger men of the present time: it was not so innocent as it had been represented. Within a few days a woman had been brought to him to have a fœtus removed. She was somewhat undersized, but the pelvis was normal, and he saw no reason for inducing abortion. When she was informed of this she began to cry, and explained that she had been under great anxiety because her dearest friend had come to the city to be relieved of her baby, and mother and baby were brought home in a coffin. Yet that abortion had probably been induced with great skill. He could recall another case: the uterus was emptied surgically, was packed with gauze; the work was done admirably, and the uterus needed to be emptied: but in spite of the gauze packing there was such hemorrhage that for twenty-four hours the woman was between life and death. He could not help believing, therefore, that unless all these cases were treated by one man such accidents would occur.

Dr. Lusk had been accustomed to Barnes' bags, and liked them, but when Dührssen's incisions were introduced he thought he would use them in order to save time in urgent cases. But, being cautious, he had waited and watched the discussions upon the method since, and had found that not all of those who had tested it had been satisfied with the result. There had been cases of severe and even fatal hemorrhage. He was glad to hear Barnes' bags referred to to-night, as one might have supposed that to some their existence was unknown.

Toxæmia of Pregnancy Divided into Mild and Severe Forms.—Dr. James W. McLane said the cases under discussion had presented themselves to him in two grades. The first, perhaps the most common variety, were cases of mild toxæmia associated with slight albuminuria. These, he supposed, were the cases to which Dr. Lusk had just referred, in which the amount of albumin in the urine was small: there were few nervous symptoms, and the patient, if carefully watched and kept on a milk diet, usually went on through her pregnancy with safety. Possibly as she neared the end and her diet was not restricted, she might show some nervous symptoms which would require interference, but by that time the fœtus was viable and could be removed by the induction of labor. He was not in the habit of treating such patients medicinally. He simply put them on a milk diet and confined them abed a part of the day, for it seemed that if any one thing would increase the albumin in the urine of these patients it was overexertion, especially in walking. There was no objection to their driving out. The bowels were kept free, and the skin active by a daily bath.

Eclampsia not Altogether a Preventable Disease.—The other class of cases was quite different from those just described, and Dr. McLane could not agree with those who believed that eclampsia was altogether a preventable disease. He had seen patients in whom the most careful examination of the urine two or three days prior to the breaking out of the eclamptic seizure failed to reveal anything. He was unable to see how in such cases the accident could be considered preventable. The toxæmia in them was probably compound, for he did not believe we had yet discovered the particular poison, if there was one, which caused the eclamptic seizure. He thought we might well believe that it was made up of a number of toxins, that these were present in the blood during pregnancy, and something, the nature of which we did not know, might be added to them suddenly and produce the explosion. We saw some of these cases just before the convulsion,

and in them we found a hard, full, bounding pulse, a flushed face, usually severe headache, dimness of vision, possibly vomiting, and all within the course of a short time. Personally he knew of nothing which gave so good results in such cases as the immediate abstraction of blood. He preferred venesection to cupping, taking away from twelve to sixteen ounces. He did not mean to say that the venesection would cure the patient, but it gave time in which to do what else was necessary. He would call this the acute variety of cases.

Dr. McLane was a firm believer in the induction of premature labor, but he also believed in watching the case and carrying it along to the period of viability, when the child could be saved. He did not believe at all that the child was damaged by the mother's condition. Some of the best children whom he had watched growing up in the city were children whom he had brought into the world prematurely for this very condition. One woman had twenty-seven convulsions, yet he delivered her prematurely of a vigorous child.

One method of treatment which had not been mentioned, but one from which he had obtained excellent results, was to rupture the membranes and let the waters escape. The action seemed to be similar to that of venesection. Thus obtaining immediate relief, one could then proceed to delivery.

He had been very much surprised at Dr. Grandin's statement with regard to the facility with which the cervix could be dilated in cases of eclampsia. Such had not been his experience. He had seen cases in which it was impossible for the strongest hand to effect dilatation within thirty minutes except by rupture of the uterus; and he had seen the uterus ruptured under such circumstances. He did not believe it was good practice to proceed in this manner, for the reason that these patients were in a state of wonderful nervous tension, and even the passage of a catheter without giving chloroform, or a vaginal examination, would bring on a convulsion. To attack the uterus in this vigorous manner must disturb the nervous system very much. He would prefer to proceed by a gentler method to get the uterus open, by the use of Barnes' bags.

After delivering the woman he allowed her to bleed a little from the womb, had some one sit by the bedside and, when a seizure threatened, give her a few drops of chloroform to inhale. Meanwhile she was rolled up in a hot pack, hot salt water was thrown up the bowel, and the action of the chloroform was promoted by morphine. He had had no experience with veratrum viride, for he had not seen a woman with a pulse after labor and convulsions to whom he would like to give this drug. At first the pulse was strong and full, but after the seizure it was anything else; it was small and feeble.

The temperature was a guide to prognosis. It was high when the patient was going to die. He had seen it as high as 107° F. in the rectum before death, and 108° F. an hour after death.

In conclusion he said that the impression which these cases had always made upon him was that the sooner we got the child out of the uterus the better for the woman, provided the means which we employed were not too severe; that the women who had done best were not those who had been treated by rapid, forcible dilatation, for they were the ones whom they had lost in the hospital—some from rupture of the uterus, some from shock.

Regarding pilocarpine, he had supposed it had been dismissed from obstetrics. He regarded it as one of the most dangerous drugs in the pharmacopœia, and since we could get diuresis without it he thought it was best, for him at least, to let it alone. He had known it to produce fatal œdema of the lungs in one woman who had a fair chance to recover.

Dr. R. A. Murray said he also had found the quickest effect from rupture of the membranes, thus relieving tension. Next in value was withdrawal of blood from the arm. In one or two cases he had stopped the convulsions by using the catheter to withdraw urine which had been retained by pressure of the womb upon the vesical neck. The specific gravity of the urine should be considered in relation to the quantity passed daily. He fully agreed with Dr. Grandin with regard to manual dilatation and rapid delivery. He had accomplished it in less than an hour in three different cases within the past six months, for threatening convulsions in primiparæ. But thirty minutes were required in one case which was more urgent than the others. He would defy any man to rupture the uterus with the fingers. But it could be done in extracting the child. Chloroform and previous venesection aided greatly in getting the dilatation up to the point where the two fingers could be introduced. If time would permit, Barnes' bags should be used. After dilatation had been thoroughly accomplished, delivery should be made rapidly under chloroform, else the cervix would recontract.

Dr. Murray could not agree with the last speaker that the convulsions in the mother did not harm the child. He had seen eclamptic seizures in children, similar to those which had occurred in the mother, several days after birth. In a paper which he had once read, the fact was pointed out that more of these women who survived had Bright's disease subsequently than of those women who passed through pregnancy without a convulsion.

Thirty Minutes Enough.—Dr. P. A. Harris agreed fully with Dr. Davis, that children born of women suffering from the toxæmia of eclampsia had diminished vitality and gave more than the average mortality. He had resorted to incisions of the cervix in only one case, that of a woman on whom trachelorrhaphy had been performed, leaving the cervix rather close and demanding the incisions to start dilatation. Regarding manual dilatation, he had published a method at the first Pan-American Medical Congress with which he had since had considerable experience. Only last March he had read a paper before the Philadelphia Obstetrical Society, containing the histories of ten cases in which he had employed the method, four for eclampsia, six for placenta pravia. In only one was more than an hour, seventy-five minutes, required for both dilatation and delivery. Usually only fifteen to twenty minutes were required for dilatation, and twenty to twenty-five for delivery, including extraction of the placenta. Only one mother was lost, the cause of death being the disease, not any accident connected with delivery. He thought Dr. Grandin ought to be supported in his remarks on rapid delivery by those who had had similar experience with some manual method.

Rapid Dilatation Failed.—Dr. Bernard Gordon said he knew of a case in which four physicians tried rapid manual dilatation: all failed. They found the os too rigid, and, fearing hemorrhage if incisions should be made, they performed Cæsarean section. The mother and child died. The statement that the physician would be to blame, if a woman under his observation should die of eclampsia, was unjust to the profession, since we knew not the cause of eclampsia.

Dr. J. Clifton Edgar, in closing, said: "We are very grateful to the various speakers for the general discussion which the paper has called forth, and to Dr. Davis in particular, for referring to the train of nervous phenomena as symptoms of the pre-eclamptic condition which were omitted in our paper. Our answer to him is that we have come to rely so much upon

the physical signs that the nervous symptoms seemed of minor importance. Still, we admit that these very nervous symptoms which Dr. Davis has so graphically described are in some instances the earliest clinical index of an approaching eclamptic seizure that is offered us.

"Regarding the use of the hydrostatic bags of Barnes, we have found them of use only as preliminary measures, namely, to prepare the cervical ring for a more rapid and thorough subsequent dilatation.

"Cæsarean section, as a means of rapid delivery in the presence of an eclamptic attack, we absolutely reject. Charpentier shows, as we pointed out in our paper, that the operation still carries with it a maternal mortality of 36.26 per cent., in eclampsia. Moreover, in the absence of pathological conditions of the cervix, we believe there is no cervix that cannot be dilated either by manual methods or by incision in time to meet every indication.

"We are in accord with Dr. Davis as to the value of atropine given by needle, not only for the œdema of the post-eclamptic state, but also for its ante-eclamptic action. The point to which Dr. Davis refers, and which we wished to make the prominent one of our paper, was that the only successful preventive treatment of puerperal eclampsia rests in the early recognition of the pre-eclamptic state, as shown in the early diagnosis of eliminative insufficiency.

"The axiom that it is far better for the patient suffering from eliminative insufficiency to induce labor too early rather than too late, which Dr. Jewett has proposed, we are quite in accord with. We notice that Dr. Jewett, of all the gentlemen taking part in the discussion, is the only one who has referred to the stupefying effects of chloroform. This we touched upon in the paper, and we believe it should be given greater prominence. Our experience has satisfied us that the less anæsthetics and narcotics the patient receives, the better the prognosis. Not only chloroform, but morphine, chloral, and the bromides deepen the post-eclamptic stupor and coma and increase the tendency to death during the coma, by reason of these drugs interfering with the eliminative processes. We have made reference to the practice of certain maternities, as reported at the last international congress, where chloroform has been absolutely abandoned as an anti-eclamptic, except when operative interference was demanded. The secret of success here, as in the preventive treatment, is an early and thorough eliminative treatment. We firmly believe that close observation will convince any one of the stupefying effects of even small doses of chloroform, given as an anti-eclamptic. For this reason we relied as much as circumstances would permit upon veratrum viride, which drug not only controls the convulsive seizures, but acts at the same time as a diaphoretic and diuretic, thus fulfilling two of our conditions at one and the same time.

"The statement made by one of the speakers, that all cervices after the seventh and a half month will yield to a manual dilatation and allow of the uterus being emptied within thirty minutes, we believe is a dangerous teaching and should not be permitted to pass without question in a meeting of this Academy of Medicine. It is to such statements that the accidents referred to in the paper are due, and it was against the careless undertaking of the rapid dilatation, without taking into account the condition of the cervix uteri at the time of operation, that we protested in our paper. Further clinical experience we are sure will cause the speaker to modify his statements.

"We agree with Dr. Lusk that the daily amount of urea excreted is not always a reliable clinical index of impending renal inadequacy and eclampsia.

"It is not one physical sign but all of them, and the symptoms as well, that must be weighed in the balance before we can decide upon such operative interference as induced labor. To secure an early evacuation of the uterus as a preliminary measure, a Barnes' bag, we believe, will do all that has been claimed for it. To secure full dilatation of the os, so that the fœtus can be extracted with safety to itself and its mother, we look upon the Barnes' bag as entirely inadequate, and not to be compared to the careful bimanual stretching and paralyzing of the cervical rings. Dr. Murray's statement, that it is impossible to rupture the uterus during the performance of a manual dilatation, is answered by the instances of partial and complete rupture of the uterus referred to in the paper. With Dr. Harris' method of digital and one-handed dilatation of the os we are familiar, and have given it trial in hospital practice. The method of operation has to do with the personal equation. For ourselves we have found the bimanual method, as depicted in the diagrams, most satisfactory, for reasons stated elsewhere, but especially for the one reason that by this method we can produce complete paralysis of the external ring of the os, which by Dr. Harris' method we have been unable to accomplish.

"Dr. McLane has referred to the value of uterine bleeding in the third stage as helpful in lessening the severity of subsequent eclamptic attacks. We believe the practice of allowing the uterus to remain lax and bleed a most excellent one, and it often takes the place of medication to reduce arterial tension.

"We cannot subscribe to the practice of an early rupture—in the first stage—of the membranes as an anti-eclamptic. We grant that the rupture of the membranes at this time apparently temporarily controls the convulsions, but our experience is that subsequently the presence of the fœtus in the uterus, not surrounded by its cushion of liquor amnii, is a greater source of peripheral irritation than when the membranes are intact and the liquor amnii is present. The worst instances of eclampsia, brought in as emergency cases to our maternity hospitals, have been those in which the membranes have ruptured early spontaneously or have been artificially ruptured in the first stage. Moreover, the subsequent labor is prolonged, and the difficulties and dangers of operative interference are enhanced by such a procedure.

"We make the same objection to the continued use of chloroform and morphine in the post-partum state as anti-eclamptics, as in pregnancy or labor. Not but that they serve as well in some instances, but, as we said before, the less the patient receives and the more attention we pay to elimination—bowels, skin, liver, kidneys—the better the prognosis.

"It is the experience of most observers that the high arterial tension does not always diminish or disappear after one or two eclamptic seizures. We have seen many cases and reported several in which the high tension persisted for days and even several weeks, and the continued use of glonoin and veratrum viride was necessary to combat this symptom and prevent subsequent eclamptic attacks.

"Pilocarpine, as we stated in our paper, we utterly reject in the presence of an eclamptic attack. To assist us in the treatment of the eliminative insufficiency of pregnancy, namely, in the preventive treatment of eclampsia, we believe we have a valuable adjunct in the muriate of pilocarpine. We have two patients at present in private practice who occasionally present the clinical picture of the eliminative inadequacy of pregnancy, as shown by an examination of the urine and the general physical signs and symptoms already referred to. In these a restricted diet and an occasional dose at bedtime of pilocarpine, calomel, digitalis, and squill, act most happily, and the stimulation of the skin, kidneys, bowels, liver, by

this combination, removes for the time being all unfavorable symptoms. We have seen no unpleasant or dangerous symptoms follow its use in this manner, for two years past.

"That eclamptic women do best in whom a rapid dilatation of the cervix and evacuation of the uterus are not performed is, as we have stated, the teaching of Charpentier, of Paris, and, as the reports of the last congress show, he stands almost alone in the world in this position. The more clinical experience we have, the more we study these eclamptic cases, the more convinced are we of the truth of Dührssen's statement made several years ago, namely, that in ninety per cent. of eclamptic cases the danger is practically over when the uterus is rapidly emptied early in the attack. Moreover, we are firmly convinced that a careful study of the anatomy and physiology of the pregnant and parturient cervix, and of the various methods of intelligent, scientific, and rapid dilatation of the same, will satisfy any unprejudiced observer that the operation can not only be performed without any additional danger to mother or child, but that it is a life-saving procedure for both parties concerned."

Stated Meeting, December 17, 1896.

Joseph D. Bryant, M.D., President, in the Chair.

A Trustee's Resignation Rejected.—Dr. J. P. Tuttle, who had been appointed at the last meeting to wait on Dr. Jacobi and learn whether his resignation as member of the board of trustees was unalterable, reported that he had called on Dr. Jacobi, and had been informed that his reason for resigning was simply that the affairs of the academy under the presidency of Dr. Bryant were running so smoothly that he felt his services were no longer needed. Dr. Tuttle recommended that the resignation be not accepted.

Dr. Jacobi, being present, said that the explanation as stated by Dr. Tuttle was strictly true. Moreover, he felt sure that the affairs of the academy would continue to run just as smoothly under the incoming administration. Of course, however, if the academy wished him to serve, he would do so with pleasure.

The motion to adopt Dr. Tuttle's report, not to accept Dr. Jacobi's resignation, was carried unanimously.

The Essential Nature of Croupous Pneumonia.—Dr. Andrew H. Smith read a paper with this title (see p. 1).

Dr. Kinnicutt, in opening the discussion, said that he had listened with great interest to Dr. Smith's presentation of his ingenious theory in regard to the essential nature of pneumonia. Without entering upon a discussion of the exact pathological process produced in the lungs by the diplococcus lanceolatus, he was unable to accept Dr. Smith's explanation of the cause of the crisis. Experimental investigations in animals pointed rather to the gradual elaboration of an antitoxin capable finally of neutralizing the toxic products of pneumococcal life. With complete neutralization the crisis occurred. He could see no other way of explaining the immunity conferred upon susceptible animals by the subcutaneous or intravenous injections of large quantities of filtered bouillon cultures of the pneumococcus, and also the immunity secured by the introduction into the blood of susceptible animals of the serum of animals already rendered immune. Within the past year Foà had published the results obtained by himself in this field of investigation, which were corroborative of those reported by other observers. He had used in his experiments cultures of the pneumococcus diluted with Lugol's solution. He had succeeded by this method in immunizing rabbits to the degree that they withstood the injection of one hundred and sixty cubic centimetres of a culture of which one-two-thousandth had proved fatal to unprotected animals. Moreover, in simultaneous injections of virulent cultures and serum from immunized rabbits, the animal lived, and a similar result was obtained when the serum was injected into unprotected rabbits five hours subsequent to the introduction of the virulent cultures. If these observations were correct, they certainly seemed to demonstrate the elaboration of an antitoxin capable of neutralizing the toxic products of pneumococcal life.

Dr. Walter B. James doubted whether pneumonia could be excluded from the list to which the inflammatory diseases of germ origin affecting other organs belonged. The difference was due chiefly to a difference in anatomical structure: the lung being more spongy was less pressed upon and less damaged by the inflammatory exudate. No doubt this exudate did form a favorable culture medium, but when it was suggested to treat the disease by inhalation of bactericidal substances the prospect seemed to be a cheerless one. The subject was important enough, however, to justify attempts at clearing it up by new theories as to the essential nature of pneumonia.

Clinical Experience with Infectiousness of Pneumonia.—Dr. John H. Girdner said his interest in croupous pneumonia dated back eighteen years, when he wrote a graduating thesis on the subject, "Is Croupous Pneumonia a Communicable Disease?" He thought even at that early date that it was, and presented in favor of that theory the fact of its resemblance in many respects to other known infectious diseases, such as typhoid fever. Subsequent experience had convinced him of the correctness of that view. A young man to whom he was called was ill with the initial chill of pneumonia. He was attended by a nurse and an uncle, both of whom were in the habit of supporting him while raised in bed, to enable him to cough and expectorate. In this position the patient repeatedly coughed in their faces. Dr. Girdner warned them of the danger. On the fifth day of the young man's illness the nurse had a chill, the initial one of pneumonia, and died four days later, or three days after the death of the young man. The uncle also contracted pneumonia and died after five days' illness. Since then, Dr. Girdner had made it a rule to destroy the sputa of pneumonia patients with the same care that he disposed of the discharges in typhoid fever. He took as much care in examining patients sick with pneumonia as in examining diphtheritic patients.

Pneumonia Always Interesting.—Dr. A. Alexander Smith said that, studied from any standpoint, pneumonia was always interesting. Personally, he had felt for a long time a great deal of interest in its study from the standpoint of the circulation, and he was under obligation to the author for bringing the subject up in this manner. The most direct statement which had been made, and the one to which he would be most inclined to take exception, was that pneumonia was a disease unaccompanied by inflammation. He saw no objection to the view that the exudate thrown out was a culture medium. It was the life history of micro-organisms that they found a culture medium in which to develop, that they there produced a toxin, and he had long been of opinion that the disappearance of the constitutional disturbance was due to the action of an antitoxin when the decline was of the character seen in pneumonia. We had been told that two-thirds of healthy people had in their bodies the pneumococcus, which was ready to attack and multiply whenever favorable conditions presented themselves. Men went on a spree, jumped off a dock, were fished out, taken to a hospital, put to bed, and in twenty-four hours we were pretty certain to find evidences of pneumonia. He thought the author had made suggestions which offered a very plau-

sible explanation of the development of pneumonia under such circumstances. There was not only depression of the system, but engorgement of the pulmonary capillaries. Regarding treatment of pneumonia by inhalations, he must confess to scepticism; still, having been sceptical before when subsequent experience had proven the value of remedies, he was willing to make the test with regard to this one.

Dr. W. H. Porter was not willing to give up the inflammatory theory of pneumonia. The products were characteristic of inflammation. He had looked upon the bacteria and the culture side of the disease as belonging to the etiology rather than to the pathological process itself. There were, he thought, three factors in the production of pneumonia: 1. Lowering of the vitality; 2. chilling or other cause of congestion or injury of the lungs, producing slight oozing, this acting as a culture medium for the germs; 3. the development of toxins. When the pneumonia had run its course, the anatomical structure of the lung was such as to favor rapid disposal of the exudate.

Dr. A. Jacobi said he was willing to try the treatment of pneumonia by inhalation of a mixture of sixty parts of chloroform and fifty parts of alcohol, as described by Dr. Smith, but there were reasons why he did not believe it would prove efficacious. The principal one was that the microbes lay in the lining cells and could not be reached unless the disinfectant or bactericide first destroyed the cell and the individual. This was true of the streptococcus in the throat, where one might suppose germs could be more effectually attacked than in the lungs. Regarding inflammatory exudative process, we need not be astonished at seeing it in the lung, for we also saw it in the areolar tissues in streptococcic invasion of the throat, with enlarged glands, etc. As to etiology, pneumococci were not the only germs capable of causing pneumonia, and to treat all cases by inhalations successfully would require an agent which would kill the several varieties of germs causing pneumonia. Usually these germs entered through the bronchi, but sometimes it was through the blood, as in pneumonia complicating puerperal fever or other diseases. The microbic cause was different, but in all there were the same results of inflammation, consisting in the migration of blood cells, throwing out of fibrin, etc. It seemed to Dr. Jacobi that the old treatment would still hold good, namely, to fortify the body and strengthen the heart until the antitoxin was formed, the progress of the disease ceased, and the materia peccans was absorbed.

Dr. Lambert reviewed in part the subject of germ etiology of pneumonia and the action of the toxins.

Dr. Andrew H. Smith closed the discussion. In reply to Dr. Kinnicutt, he reminded him that inoculation with a pure culture of pneumococcus lanceolatus did not produce pneumonia unless it was made into the lungs. In their objections to treatment by inhalations, all the speakers seemed to have overlooked the point that the treatment should be begun early, before the air cells had become entirely occluded, and while the inhaled gas could still reach the cells and germs. It should be remembered that chloroform when inhaled penetrated everything and was taken into the circulation. It was not claimed that it necessarily reached and killed the germs directly, but it rendered the culture medium unacceptable, for the pneumococcus was exceedingly sensitive to environments. Regarding an antitoxin, if defervescence were due to this, why was it so variable, being in some cases by lysis instead of by crisis?

The Permanganate Treatment of Opium Poisoning.—Dr. William Ovid Moor read the paper. "Opium is undoubtedly one of our most important and most frequently used remedies, and it is just for this reason that accidents in connection with its general and frequent use are of daily occurrence. The number of deaths caused annually by the products of papaver somniferum is great. In England and Wales six hundred and forty-six persons died from opium poisoning between 1883 and 1887 (inclusive). Dr. Barker Smith, of England, has estimated that in the last ten years the world over about one hundred thousand persons have succumbed to opium narcosis. It is therefore certain that the knowledge of a prompt and safe antidote to opium is a matter of primary importance. Emetics cannot be called antidotes in the true sense of the word: besides, they are utterly unreliable in narcotic poisoning, and are simply inducive to loss of precious time.

"As to atropine, many authorities, among them Brown-Séquard and J. Harley, dispute an antagonism between these two narcotics. Harley concludes that in medicinal doses the essential effect of morphine (hypnosis) is both increased and prolonged by the action of atropine, whether introduced previously or at any time during the operation of the former. On the other hand I can state with the utmost confidence that I have found in potassium permanganate the true antidote to opium and its alkaloids. For several decades past the salts of permanganic acid have been recommended as antidotes to organic poisons in general, which naturally includes alkaloids. Permit me to demonstrate to you that such a claim is erroneous."

The author showed that no reaction takes place between permanganate and atropine, cocaine, veratrine, pilocarpine, aconitine, caffeine, hyoscyamine, hyoscine, and phosphorus.

"The permanganate acts quicker on albumin than on strychnine. I have found that it scarcely oxidizes phosphorus even after sixteen hours' contact. I will show you now that the reaction between permanganate and morphine is instantaneous. One grain of the potassium salt oxidizes one grain of sulphate of morphine. The permanganate is decomposed into potassium hydroxide, hydrated manganese dioxide, and oxygen. The morphine is changed into a substance akin to pyridin—tricarboxylic acid. Yet the mere fact that $Mn_2O_5K_2$ oxidizes some chemical substance is no proof that the product resulting from this chemical reaction is not toxic. The following case well illustrates this statement.[1] At the clinic of Dr. Harnack in Halle a girl, fourteen years of age, was treated for general eczema. On one occasion she was given tannic-acid applications to her arms and at the same time she was ordered a permanganate bath. Violent fever and profuse diarrhœa set in. The tannic-acid applications were stopped but the permanganate treatment was continued and after eight days the patient's condition was normal. Urinary analysis showed the presence of pyrogallol, which must have been formed through the oxidization of tannic acid by the potassium salt. The clinical picture corresponded to pyrogallol poisoning, the chief symptoms of which are fever and diarrhœa.

"The principal point for me to determine was whether or not the oxidization of morphine renders it innocuous. The experiments for this purpose were made chiefly upon myself. This was necessary when we consider the low degree of susceptibility of animals to opium. Having found that the permanganate will oxidize morphine in an albuminous solution, I could swallow with impunity gradually increasing doses of morphine followed in a few moments by corresponding amounts of the potassium salt.

"On the 20th of January, 1895, I took, about two hours after breakfast, five grains of sulphate of morphine, followed in a few moments by eight grains of the antidote dissolved in eight ounces of water, without experiencing any effect whatsoever from the narcotic.

[1] Deutsche med. Wochenschrift, 1895, No. 1.

Had only one-eighth of a grain of morphine been absorbed into the circulation, I should have felt it undoubtedly, as I am very susceptible to the action of narcotics. It is by no means a condition *sine qua non* that the antidote must be given immediately after the ingestion of the poisonous dose of morphine, as has been claimed, for morphine is not a corrosive substance like carbolic acid or the mineral acids. We should not forget that as soon as opium begins to exert its narcotic influence, gastric and intestinal activity is greatly reduced, and, consequently, the absorptive power of the gastric mucous membrane is very much lessened. It is, therefore, not surprising when we hear that considerable quantities of opium or morphine have been found in the stomach of persons who have died from this poison.

"We have, therefore, no right to assume that no more poison is in the gastric cavity of the patient because a considerable time has elapsed since its ingestion. In connection with this point there is another important topic I have to dwell on. It is now a well-established fact that morphine which is injected subcutaneously is excreted by the mucous membrane of the stomach. Hitzig, of Halle, by washing out the stomach of animals that had received morphine subcutaneously, succeeded in obtaining fully one-half of the injected amount during the first hour after the injection. It is a logical necessity that an antidote which acts instantaneously must destroy in the stomach a certain amount of poison that got into the circulation either through hypodermic injection or through absorption by the stomach, for it is evident that the same circulation which conveys the poison from the peripheral parts of the body to the stomach must also bring back to the latter a part of the poison which previously was absorbed by it. In connection with this it is of interest to cite a case mentioned in the *American Journal of the Medical Sciences*, January, 1895:

"A Chinaman had taken the estimated quantity of one hundred and fifty grains of opium at 10 A.M. At 5:30 P.M. the stomach was repeatedly washed out, until there was reason to believe that there was no longer any opium contained therein. A second lavage was made at 8 P.M., and a third at 11:30 P.M., a quarter of an hour before his death. The second washing came out colorless, although it gave fine alkaloidal reactions, but did not respond to the test for meconic acid; the third, also colorless, gave good reactions. The first washing removed the ingested but unabsorbed opium, but the alkaloids found in the others could have been detected only through their excretion by the gastric mucous membrane.

"The following case, reported by Dr. Hari Bhicaji, chief medical officer in Goudal, Kathiawar, East India, illustrates that the internal administration of our antidote is life saving even after a considerable time has elapsed since the taking of the poison.

"'A Hindoo child, about eighteen months old, while playing in the house, accidentally came upon the father's opium box and swallowed a four-grain lump of opium which he found in it. This occurred about noon, while the mother was out on some business. On her return at 2 P.M. the mother found the child lying unconscious on the ground, with the tin box beside her. The mother ran at once with the child to our hospital, and when admitted the child was fully under the influence of opium. The case seemed a hopeless one, as the symptoms of poisoning were most profound, and there seemed no chance of hope by using the stomach pump or by giving emetics. The idea then occurred to me that permanganate of potash, as recommended by Dr. William Moor, of New York, might answer in this case. Accordingly I dissolved eight grains of the permanganate of potassium in one ounce of water, and began to administer the fluid with much difficulty, a teaspoonful every ten minutes. After half an hour from the first dose, the child appeared to improve. The solution was continued, but it was now given in the same dose every twenty minutes. Gradually but visibly, without emesis, the narcotic symptoms gave place to returning consciousness, quiet, natural respiration, and voluntary motor power, so that about midnight the child was seen playing in bed by the side of its mother, perfectly restored after sixteen grains of permanganate of potassium had been administered.'

"It is evident that in this case and in other reported cases of a similar nature the antidote acted first by oxidizing the poison still contained in the stomach and then by annihilating the alkaloids which returned from the circulation to the stomach.

"One of the most interesting features relating to the use of the opium antidote is the beneficent effect observed from its hypodermic administration. Rabbits which had received hypodermic injections of one to three grains of morphine were greatly improved by the hypodermic administration of the antidote, both as to their respiration and their general condition. I have published the details of these experiments in the MEDICAL RECORD of March 2, 1895. I shall cite a few cases in which the subcutaneous injection of the antidote was of unmistakable efficacy.

"The question arises: What is the *modus operandi* of the hypodermic use of our opium antagonist? First, I thought that the antidote selected the morphine from among the albuminous constituents of the blood. To this view it has been objected that the permanganate is rapidly decomposed by the subcutaneous tissues, and thus could not reach the circulation in an unaltered condition. I must confess that I have fully realized the correctness of this objection. For the same reason I have also abandoned the idea that the permanganate converts hæmoglobin into oxyhæmoglobin. Professor Hare, of Philadelphia, suggested that the pain due to the hypodermic injection of the antidote acted as a stimulus to the respiration. But when we consider that an improvement in respiration took place in many cases in which there was absolute insensibility to pain, Dr. Hare's view appears fallacious.

"From a careful analysis of the cases reported, it has become evident to me that the action of hypodermic injections of permanaganate is a physiological one, and probably is effected by the absorption of small quantities of hydrated manganese dioxide. We know that some ingredients of the blood exert at times a dynamic function. Buchner, of Munich, has shown that blood serum loses its germicidal capacity if chloride of sodium is abstracted from it. Yet a physiological solution of common salt is certainly not a germicide.

"Referring this example to our subject, we can say that the presence of a small quantity of manganese in the blood may dynamically increase the oxygen capacity of the blood and may render more stable the combination of oxygen and hæmoglobin. Dr. Sharp, of Philadelphia, made animal experiments with permanganate and opium, and came to the conclusion that the hypodermic injections acted physiologically. These observations justify me in making the statement that the hypodermic administration of weak permanganate solutions should be of benefit in all cases of narcosis, asphyxia, and cyanosis.

"Gentlemen, if you have to deal with alarming cases of ether and chloroform narcosis, illuminating-gas asphyxia, asphyxia from drowning and laryngeal obstruction, uræmia, eclampsia, and cases of a similar nature, and if you have resorted without benefit to the usual methods of treatment, also administer hypodermically solutions of permanganate of potassium, which can do no harm, but may be of great benefit (1 to 100 to 1 to 500).

"About ninety or one hundred cases of opium poisoning have been reported to me, in which the antidote has proved its great value. It should be given at once; no time should be wasted with emetics and stomach pump, as an instanteously acting antidote is far superior to these. It should be given to meet three indications: 1. Per os (eight to ten grains well diluted, or more), to annihilate any opium or its alkaloids that still may be in the stomach. 2. To decompose the alkaloids which return from the circulation to the stomach. This is accomplished by giving from time to time weak solutions of the antidote (one grain to a tumblerful of water). 3. Hypodermic injections of permanganate solutions (1 to 100 or more), to act as a physiological antidote.

"I conclude by expressing the earnest hope that my words will aid in diminishing the number of serious and fatal cases due to opium narcosis and to other forms of narcosis, asphyxia, and cyanosis."

Dr. W. H. Porter said he had had no experience with permanganate in the treatment of opium poisoning, but he could see no reason why it should not render the opium which was in the stomach inert. He could not understand how it could act after the opium had been absorbed.

Dr. Andrew H. Smith said he had had no personal experience, but some time ago had directed that the permanganate be kept in the Presbyterian Hospital. A number of victims of opium poisoning had received it, and all had recovered; but in all instances O'Dwyer's bellows was also used, and he was unable to say to which agent belonged the credit. The experiments of Dr. Moor on himself and in other directions seemed conclusive.

Dr. R. W. Wilcox had felt much interest in this subject from the time Dr. Moor had first written upon it, and believed we had an agent in permanganate which was harmless in itself and destined to make us feel much more comfortable when called to cases of opium poisoning.

Dr. F. A. Burrall had been some months ago called to a man who was said to have swallowed about two drachms of laudanum by mistake, and was informed at the druggist's where he stopped on his way to the house that the druggist had sent ten grains of permanganate of potassium in solution, which the patient drank as an antidote very soon after swallowing the opium tincture. Dr. Burrall remained with him an hour, and then left, as no symptoms, not even drowsiness, developed. He thought that if permanganate should be definitely proven to be a real antidote to opium, some such rule might be established as that of requiring druggists always to dispense the antidote along with the narcotic.

Dr. Lambert mentioned a case which had occurred at Bellevue last summer, that of a man suffering from sunstroke to whom the house physician gave more of Magendie's solution to quiet restlessness than was wise—twenty to forty minims within an hour. He found the patient breathing only four times a minute. Permanganate was administered (four grains), and within an hour the respirations had increased to eight per minute, and next morning the patient was in good condition. It had struck him as rather a remarkable result to be effected by permanganate solution within the stomach on morphine which had entered the circulation.

SECTION ON PEDIATRICS.

Stated Meeting, December 10, 1896.

W. H. Fruitnight, M.D., Chairman pro tem.

Fatty Liver and Ileo-Colitis.—Dr. R. G. Freeborn said that soon after Dr. Southworth presented his case of fatty liver and ileo-colitis, at the last meeting, he had occasion to make an autopsy on a child, five months old, which had given a somewhat similar clinical history. He found enlargement of the liver with marked fatty infiltration, and the lesions of ileo-colitis. He had been impressed with the great frequency of fatty liver at the New York Foundling Asylum, where this patient was seen. In two hundred and six autopsies, the liver was plainly fatty on gross examination in fifty-seven. Most of the patients were under three years of age. But this percentage was much less than that of two foreign physicians whom he quoted, since in their autopsies in a large number of cases eighty-one per cent. had fatty liver. In tuberculosis fatty liver was said to be present more frequently than in other diseases, but Dr. Freeborn had found it less frequently than in the total of other diseases. In ileo-colitis it was present in fifty per cent. of the cases. The proportion was not much greater for all diseases in emaciated subjects than in those not emaciated.

Amaurotic Idiocy.—Dr. Heiman presented a child, fourteen months old, in illustration of the condition which he said Dr. Sachs was first among physicians in this country to describe as amaurotic idiocy, in 1886. The child, according to the parents, was normal until the age of six months, and they attributed its idiotic condition and blindness to cutting of teeth. A yellowish-white patch occupied the situation of the macula, about two and one-half times the diameter of the disc, in the centre of which was a cherry-red spot —optic-nerve atrophy. There was exaggeration of the knee reflex and ankle clonus. The anterior fontanelle was open. The condition was apt to occur in other children of a family, but in this instance the patient was the sole child of the parents. Death nearly always took place by the second year.

Statistics of Antitoxin Treatment at the New York Foundling Asylum During the Last Four Months.—Dr. J. Lewis Smith read the statistics. The number of cases of diphtheria and deaths at the asylum for the last seven years was as follows: 1890, 71 cases, 36 deaths; 1891, 67 cases, 35 deaths: 1892, 60 cases, 23 deaths; 1893, 123 cases, 34 deaths: 1894, 133 cases, 32 deaths; 1895, 94 cases, 43 deaths: 1896, until December, 147 cases, 18 deaths. Attention was called to the marked decrease in the death rate the last year while antitoxin was being used. During the last four months, under antitoxin treatment, there had been: July, 10 cases, 9 recoveries; August, 6 cases, 6 recoveries; September, 5 cases, 5 recoveries; October, 19 cases, 18 recoveries: November, 25 cases, 24 recoveries. Of these 55 cases, 12 had croup more or less developed, but only 3 required intubation. All recovered. It seemed the disease had been shorn of its terrors. He was not a partisan in the matter, and while he knew the type of diphtheria, like that of other diseases, varied from time to time, he thought that was not the explanation of the diminished mortality under the antitoxin treatment. He quoted Dr. O'Dwyer, also connected with the aslyum, as stating that by resorting to antitoxin early in diphtheria, one could nearly always avoid intubation. At the asylum they expected to see the membrane loosened in twenty-four hours; sometimes it loosened in eight hours after using antitoxin. Local treatment, especially cleansing the obstructed nostrils, should not be dispensed with.

Some Statistics of Antitoxin in Philadelphia.—Dr. Edwin Rosenthal, of Philadelphia, said that out of 166 severe cases of diphtheria which he had treated with antitoxin, 76 were laryngeal, and only 4 patients had died. In 34 intubation was required, and of these only 3 had died. These results should be contrasted with some in his experience before the introduction of antitoxin, when he had lost as many as 68 out of 100 cases. Now and then we read of a

case of rather sudden death which had been attributed to antitoxin, but Dr. Rosenthal doubted this, for he had seen sudden death before the introduction of antitoxin, simply from moving the child, or just after intubation, etc., the cause being probably heart failure. Formerly he saw no cases of recovery from diphtheria secondary to measles, whereas now, under antitoxin treatment, death was rare also in such cases. He mentioned the occurrence of diphtheria of the nose without any membrane in the throat. He had had no bad effects from antitoxin, but now and then had seen temporary eruption.

Statistics of Total Deaths from Diphtheria.—Dr. Herman M. Biggs said he could not speak of the treatment of diphtheria from personal experience, but would refer to some data which he had collected, showing the results of treatment judged by the absolute number of deaths from diphtheria before and since the introduction of antitoxin. The criticism had been constantly made by the opponents of antitoxin that the statistics collected were of little value, because they showed percentage of mortality, and this meant nothing, because the number of cases had increased or the type of the disease had changed. But so far as he knew, there was no way to explain, except it were due to the treatment, the reduction in the absolute mortality from diphtheria which had taken place the world over, as indicated by the numerous tables which he exhibited. These tables showed the total number of deaths from diphtheria for the successive years since 1889 in Paris, Berlin, New York, and in all the towns throughout France with a population above 20,000, and in Germany with a population above 15,000. In Berlin the total average death rate from diphtheria for six months for these years up to 1895 was 668. For 1895, after antitoxin had been partially introduced, it was 429; and in 1896, after more general introduction, it was only 294, or less than one-half the absolute number of deaths which had occurred on the average for the preceding six years. In Paris there had been a similar reduction: from 1889 to 1895 it had averaged 923, while for 1895 it had averaged 228, and for 1896, 329. He impressed the fact that these were not percentages of mortality in the total number of cases diagnosed as diphtheria, but the average of deaths from the disease. New York City also showed a great fall in the absolute number of deaths from diphtheria in 1895 and 1896 compared with the previous five years. Other tables showed that the good results from antitoxin treatment were greatly in favor of cases treated early. Dr. Biggs quoted, in conclusion, Virchow's exclamation, that theoretical considerations must yield to the brute force of statistics.

Dr. A. Campbell White said that in his connection with the health department of New York he had seen about 600 cases of diphtheria during 1896, and while not more than one-fifth of the number had been treated with antitoxin, yet the results were decidedly in favor of the latter. Antitoxin was not so likely to be used in the milder cases, but when the disease became severe the parents were likely to insist upon its use. As to methods of feeding, he had been much more favorably impressed with introduction of the food into the stomach by way of the nares than with rectal feeding. He had heard it said that the intubation tube, when used, had to be left in much longer in antitoxin cases; but that was contrary to his observation. He had never seen any complications. When heart failure took place, he attributed it to absorption of diphtheritic poison before the use of antitoxin. Nasal irrigation was demanded much less frequently than before the use of antitoxin.

Dr. Henry Koester had seen much of diphtheria in connection with the health department, and since April of this year had injected 93 patients with antitoxin, only 2 of the number dying. Later, or since October, he had injected 44, with only 1 death. He thought that the physician who had a case of severe diphtheria and did not use antitoxin committed a criminal offence.

The Other Side.—Dr. Joseph E. Winters thought the question of the antitoxin treatment of diphtheria would never be settled by such statistics as had been presented to-night, but must be settled by careful study of cases in private practice. As proof of the first statement, he quoted the absolute mortality from diphtheria for certain years in New York before the introduction of antitoxin, and said it had been fifty per cent. greater some years than others. So with other cities. The number of deaths from diphtheria in Philadelphia in 1888 was 350, whereas in 1892 it was 1,452. He quoted Dr. Graves, of Dublin, as Dr. Smith had done, on the variation in type of the disease. In Dublin, Graves lost nearly all of his cases of scarlet fever in the epidemic of 1801–1804. From the latter year to 1831 few patients died. From 1832 to 1835 there was another epidemic like the first one mentioned, when nearly all patients died. It meant a variation in type of disease, not in treatment. Dr. Winters gave statistics sent him by physicians in New York, showing as good results, if not better, from treatment without antitoxin than those which had been presented in favor of antitoxin. Some of the gentlemen had given up antitoxin, because its use in their hands had been attended by so high a mortality. Regarding Dr. Biggs' statistics for Paris and Berlin, showing a reduction of deaths from diphtheria for 1895-96, why had he not quoted London statistics? In that city there had been no such reduction, and yet antitoxin was employed in London as well as in Paris and Berlin. There was simply a difference in the type of the disease. In the same way, one could account for the fact that Dr. Smith could give a lower mortality for antitoxin in the Foundling Asylum than he had done for an earlier period. At the Willard Parker there had been a death rate for August, 1896, of 37.7 per cent., and for November one of 25.6 per cent. The difference was due to difference in the material. In the same hospital it was decided to try increasing the dose, which had been done from 1,500 to 6,000 units; but out of 30 patients so treated, 18 had died—a death rate of 60 per cent. Before that they had increased from 1,500 to 3,000 units, with the result of having a death rate of 50 per cent. Dr. Winters then presented the histories of a number of cases seen by him in consultation practice, in which antitoxin had been used and had been followed by tetanic convulsions, ending soon or after many hours in death: also cases of sudden death with other symptoms. A number of cases with unfavorable symptoms had been reported to him by various physicians. Such facts led him to look upon this serum not as an antitoxin, but as a toxin which added to the dangers of diphtheria. Physicians were giving it up in private practice. He had been told that druggists sold less of it, and the health department was turning out much less than it had done some months ago. One doctor could be heard to say that he would not use Behring's serum, but employed only Aronson's, having had an unfavorable result from the former. Another did not use Aronson's, having had a death which he attributed to it. And so with other serums: they were all dangerous.

Dr. Rupp related some experience unfavorable to antitoxin, and thought that physicians in private practice had good reason to take exception to the statement made by the gentleman connected with the board of health, that the doctor who failed to use antitoxin in a severe case of diphtheria was a criminal.

The discussion was continued by Drs. Berg, Bran-

NAN, WILLIAM PARK, and was closed by the author. They were of the opinion that Dr. Winters was somewhat prejudiced, otherwise he would not have overlooked the fact that the high mortality from diphtheria in the Willard Parker Hospital occurred during the month of August, when the temperature was excessive and many people throughout the city died from the heat: further, that the board of health was, it was true, turning out less antitoxin by the quantity than formerly, but it was five times stronger, and in reality was greater, measured by antitoxin units. The large doses used in the Willard Parker Hospital were for the severer cases, which would account for the higher mortality in them. Since under former treatment they would die, it was thought justifiable to try the larger doses, and the mortality had not been great on that account.

Officers.—Dr. W. H. Fruitnight was elected *Chairman*, and Dr. T. S. Southworth *Secretary* for the ensuing year.

Therapeutic Hints.

Medicated Crayons for the treatment of uterine cancer are composed of:

℞ Methylene blue,
Tannin.....āā cgm. 0.25
Powd. opium ..... cgm. 0.05
Olive oil..... gtt. xv.
Cacao butter..... gm. 4

For one suppository, to be introduced daily into the cervical canal and kept in place by means of a tampon.—*Gaz. de Gynécol.*

Diabetes.—

℞ Sodii arseniat..... gr. i.
Lithii carbonat . ..... ʒ i.
Codeinæ..... gr. iiss.
Ext. cinchonæ (dry)..... ʒ iv.
M. Make into thirty cachets. S. One to be taken after breakfast and one after dinner.

—ROBIN.

Ichthyol in Affections of the Eyes.—Dr. Germani (*Gazetta degli Ospedali*, June 20, 1896) finds that lanolin mixed with from ten to fifteen per cent. of its weight of ichthyol is very efficacious in ciliary blepharitis, curing it when the ordinary yellow ointment has failed. Collyria containing from one to three per cent. of ichthyol are very useful in phlyctenular conjunctivitis and in simple catarrhal ophthalmia. Ichthyol is well borne, soon eases the pain, and hastens the cure.

Gelanthum.—This is the name under which Unna has just put forward another of the occlusive varnish-like dressings designed for the incorporation of various remedial agents for use in skin diseases. Unlike many previously tried substances, this holds chrysarobin, pyrogallol, resorcin, salicylic acid, etc., in even suspension. The difficulty heretofore has been that they cake up or form into small masses. Furthermore, ten per cent. of fat, if first emulsified, and twenty per cent. of glycerin can be used along with ichthyol, thirty per cent., or with carbolic acid. The varnish is composed of equal parts of gelatin and tragacanth specially mixed. It is said to spread easily, to dry quickly and with a smooth surface, to be inexpensive, besides possessing the great advantages above enumerated. For further particulars see *Therapeutische Wochenschrift*, September 13, 1896.

Hydrobromate of Scopolamine has been found by Dr. Oliver (*The American Journal of the Medical Sciences*, November, 1896) of the greatest value in the treatment of plastic iritis. Its quieting properties are greater than those of atropine in similar dose, but effects are not so lasting. It is the preferable drug for quick effect in the early stages of inflammation. Alternating with atropine gives the best effects in chronic forms with subacute exacerbations. Two drops one-tenth of one per cent. strength may be given and repeated as often as three times an hour, preceded or not by two drops of a two-per-cent. solution of hydrobromate of cocaine a few minutes before each instillation when there is much pain.

Constipation in Children.—

℞ Bicarbonate of sodium..... ʒ iij.
Powdered rhubarb ..... ʒ ij.
Sulphate of sodium..... ʒ i.
Oil of peppermint..... gtt. xx.
M. S. Half to one teaspoonful before breakfast.

—*Journal de Médecine de Paris.*

Whooping-Cough in Adults.—

℞ Bromoform ..... 15 parts.
Tincture of gelsemium..... 16 "
Syrup of lactucarium..... 120 "
Powdered gum arabic..... a sufficiency.
M. S. Three or four teaspoonfuls to be taken in the course of a day.

—BANCOCK, *Semaine Médicale.*

Otorrhœa.—Cleanse the canal with a tepid four-per-cent. boric-acid solution and apply the following preparation upon absorbent cotton:

℞ Carbolic acid..... gr. xv.
Glycerin ..... ʒ v.
Pure pheno-salyl..... gr. xv.
Water..... ʒ iss.
M.

—LACROIX, *La Tribune Médicale.*

Erysipelas of the Face.—

℞ Carbolic acid..... ʒ ss.
Tincture of iodine,
Alcohol .....āā ♏ xxx.
Oil of turpentine ..... ʒ i.
Glycerin..... ʒ iss.
M. The lesions are to be painted with this liniment every two hours, and covered with aseptic tarlatan.

—*La Presse Médicale.*

An Astringent and Antiseptic Injection for Uterine Leucorrhœa.

℞ Tannic acid..... gr. dcccc.
Pure alcohol,
Creosote.....āā gr. cccl.
Distilled water ..... ʒ viiss.
M. From three to four injections a day are to be taken, for each of which a dessertspoonful of the solution is to be diluted with a pint of warm water.

—BUSTILLO LIROLA, *Gaz. Hebd. de Méd. et de Chir.*

Local Treatment for Neuralgia.—

℞ Menthol,
Guaiacol..... āā ʒ i.
Alcohol. absolut..... ʒ xviii.
A drachm of this mixture is to be rubbed lightly into the affected part two or three times a day. In the intervals a cotton dressing is employed.

—SABBATINI.

Parasiticide.—

℞ Spirits of camphor ..... 4.2 gm.
Glycerin..... 1 "
Essence of turpentine ..... 0.15 "
Mercury bichloride ..... 6 "

—HALLOPEAU.

Constipation.—

℞ Ext. fld. cascaræ sagradæ..... 100
Tinct. nucis vomicæ,
Tinct. belladonnæ.....āā 5
Tinct. badianæ..... 10
Chloroformi..... 2
M. S. Take a teaspoonful in a little water after breakfast and dinner for a week, and then pro re nata. For obstinate constipation in old men, with torpor (inertia) of gastro-intestinal tract, after all other means have failed.

—J. DIAS RIBEIRO.

Intestinal Fermentation with Constipation.—

℞ Ext. aloes. . . . . gr. vi.
Pulv. rhei. . . . . gr. vi.
Benzosol. . . . . gr. ix.
Ext. hyoscyami. . . . . gr. vi.
Misce et ft. caps. No. xii. S. One after meals.

—Thomas Hunt Stuckey, *American Therapist*, August.

Vaginal Suppositories.—

℞ Acetanilid . . . . . gr. lxxv.
Tannin. . . . . gr. viij.
Extract of hyoscyamus . . . . . gr. iv.
Sugar of milk. . . . . gr. cl.
M. This is for one suppository, to be used for vaginal inflammation.

—*Journal de Médecine de Paris.*

Solvent for Sordes.—

℞ Acidi borici . . . . . gr. xxx.
Potassii chlorat. . . . . gr. xx.
Succi limonis. . . . . ʒ v.
Glycerini . . . . . ʒ iij.

—McGregor, *British Medical Journal.*

Goitre.—The *Revue de Laryngologie* says that good results may be obtained from the parenchymatous injection of one-fourth to one drachm of a mixture composed of the following:

℞ Iodoform . . . . . 1 part.
Sulphuric ether. . . . . 7 parts.
Olive oil. . . . . 7 parts.

—C. Gabre.

Beriberi.—

℞ Aquæ 150
Tinct. scillæ 8
Tinct. digitalis 2
Syr. quininæ 3
Ammoniaci (liquid). . . . . gtt. xij.
M. S. Two tablespoonfuls in water every three hours.

—J. Dias Ribiero, *Dunglison's Coll. and Clinical Record.*

Cardiac Diuretic.—

℞ Theobromine . . . . . gr. x.
Powdered digitalis. . . . . gr. i.
Camphor . . . . . gr. ij
Calomel . . . . . gr. i.
S. In a capsule. Four to be taken daily.

—*Therapeutic Gazette.*

Diabetes Mellitus.—

℞ Lithii carbonat . . . . . gr. xxx.
Sodii arseniat . . . . . gr. i.
Ext. gentianæ. . . . . gr. xv.
M. ft. massa et in pil. No. xx. div. S. One pill morning and evening.

—Vigier, *Annual Univ. Med. Sci.*

Erysipelas.—

℞ Tannic acid,
Camphor . . . . . āā 4 parts.
Spirit of ether. . . . . 30 "
To be applied hourly for four or five times.

—Rehbinder, *Centralblatt für die gesammte Therapie.*

Bleeding Gums.—The following is recommended as an efficient styptic:

℞ Chloroformi. . . . . gr. lx.
Acidi tannici . . . . . gr. xxx.
Menthol . . . . . gr. xxx.
Tinct. kramerie . . . . . ʒ i.
Aquæ dest . . . . . q. s. ad ℥ i.

—Vian, *N. E. Medical Monthly.*

Early Stage of Gonorrhœa.—

℞ Acidi carbolici. . . . . ♏ xx.
Opii aquosi ext. . . . . gr. xx.
Acidi borici . . . . . ʒ ss.
Liq. plumbi acetatis. . . . . q.s. ad ʒ vi.

—Martin.

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

THE ELECTION TO THE COUNCIL—CAMBRIDGE UNIVERSITY DR. CULLINGWORTH'S CASE—MR. ANDERSON'S JENNER MEMORIALS—THE QUEEN'S REIGN CELEBRATION—OYSTERS AND DISEASE—THE B. M. J.'S NEWS AND ADVERTISING—HOSPITAL REFORM—CHARING CROSS—DENTAL HOSPITAL.

London, December 11, 1896.

As I predicted, the midwives question has dominated the election to the Medical Council. The successful candidates are Dr. Rentoul, Mr. G. Brown, and Dr. Glover. The first on the poll is Dr. Rentoul, the man who has most actively defended the profession against the intrusion of an army of midwives. Mr. Brown spoke out on this question and generally upholds the rights of the general practitioner. Dr. Glover's views were not quite satisfactory, and he descends from the top to the bottom of the poll after ten years' service. You will see that the general practitioners have placed three of their own order in the council. Many regret that Mr. Rivington was not successful, for, although a consulting surgeon, he has always defended the rights of the G. P's and has been known as an advanced reformer for some thirty years. It is satisfactory to many that the profession refused to be dictated to by the journals. The association candidates have failed, and this time Dr. Glover is saved from defeat by his ten years' record rather than by his position on the staff of *The Lancet*.

There has been a warm controversy at Cambridge about the appointment of a successor to the late Sir George Humphry in the professorship of surgery to the university. There are some difficulties, as the hospital is independent of the university, but arrangements have been made in other cases for harmonious working and no doubt could have been again. Differences of opinion arose as to the best course to take and eventually the appointment was postponed for a year. This seems a curious procedure for the far-famed university, and if the duties of the chair are so important how are they to be discharged during the interregnum?

The subscription to defray Dr. Cullingworth's legal expenses is a magnificent success. Already the whole amount has been promised and the list closed. This shows how keenly the danger has been appreciated. One or two anonymous voices have been raised to damp the enthusiasm, but have only met with contempt.

I wish the fund for Mr. Anderson's appeal went on as merrily. He is the victim of a judicial outrage which might happen to any British subject until the judgments are reversed or the law is changed, and yet the civil-rights defence fund languishes. It seems a scandal that after a British jury has pronounced his oppressors guilty and awarded him damages, the right of judges to do wrong should stand between the persecutor and the victim.

The fund started by the Epidemiological Society for establishing a Jenner medal has already reached between £60 and £70. Subscriptions are limited to one guinea. A national memorial has been started. On Monday there was an influential meeting for this purpose at St. George's Hospital, of which Jenner was a pupil, when a strong committee was appointed. Lord Reay represented the University of St. Andrews, of which Jenner was a graduate. A public meeting is to be called early in the coming year to decide what form the memorial shall take. It was proposed to connect it with the Institute of Preventive Medicine, but there is a small and noisy faction which objects to

experiment and will perhaps take the opportunity of opposing the celebration of the centenary. Though Jenner was the real discoverer of the immune condition which has been developed in our own day, his real work was not such as the public will associate with that of the institute. The memorial to Jenner, if it is to be national, should appeal to the world on his merits and not be tacked on to any institution. This was felt by some present and expressed by Mr. Hutchinson, who also testified to the full vindication of vaccination by the royal commission, of which he was a member and which he said fully supported Jenner's views of the efficacy of the process, with the single qualification that it is desirable to repeat the operation at puberty. Other speakers were the bishop of Rochester, Sir R. Quain, Dr. Michael Foster, Lord Glenesk, Dr. Wilks, Prof. B. Sanderson, Prof. C. Allbutt, Dr. Glover, Lord Clifden, and Mr. T. Holmes.

There is a good deal of talk about the celebration next year of the Queen's sixty years' happy reign. A project was attributed to the lord mayor of raising £800,000 or £1,000,000 to free the hospitals from debt. This seems to have dribbled into a proposal to endow the Queen's Institute for Nurses. This institute was founded by the Queen in the jubilee year with money subscribed as the "women's offering" on that occasion. But useful as the institute is in nursing the poor, it is a small affair compared with the hospitals and not in such urgent need of money. All sorts of silly suggestions are being made to meet this need, *e.g.*, an addition to the income tax, a charge on the poor rate, and other modes of State bounty. But the hospitals will have to depend on voluntary contributions and the lord mayor might do worse than attempt the plan attributed to him of helping them.

The oyster scare has assumed a more definite position. The medical officer of the local government board has prepared a supplement to his annual report, in which the probability of infection by eating oysters is dealt with. That such infection is possible may be regarded as certain, but the probability of this occurrence will be variously estimated. A considerable section of the public has taken alarm and refuses to eat the suspected food. If this spreads further the commercial interests at stake may help to bring about the supervision for which an outcry is already raised. The general tone of the official report is somewhat more reassuring than was expected. Dr. Thorne Thorne rightly remarks that the bacteriologist can tell us of risk and impurity but not of safety and purity: so for these we must look to the conditions surrounding the culture and storage of the oysters. This is true enough, but then it is found that in some places the conditions are as alarming as they are revolting. Some oyster beds have been laid where sewage contamination was inevitable and in others occasional pollution is only too probable. Dr. Klein shows that the typhoid bacillus and Koch's vibrio may persist for two or more weeks in sea water, and the former is not prone to undergo any important change in oysters, though the latter seems to do so. I believe this limit has been found exceeded by other observers. It is being remarked by some of those interested that the chance of infection by any single oyster must be very small, as it is only in a few that pathological organisms have been detected. A similar hopeful or careless statement might be made as to other sources of infection. Now it is proved that oysters may convey disease when cultivated near sewage outfalls, danger and disgust alike at the fact of such positions having been selected point to the necessity of immediate removals.

The *British Medical Journal*, in its usual efforts at advertisement in the "lay press"—a crime it denounces fiercely in individuals—has this week made itself a laughing stock. The editor sent an advance copy of his news of the health of Dr. Jameson to the public press, which duly quoted the same on Wednesday morning; but lo! when the *British Medical Journal* came out the paragraph was omitted. So the public had in the dailies the *British Medical Journal's* latest news three days in advance of its own subscribers and these latter do not get it at all in their own organ. So much for the gratuitous advertisement of a journal, which is repeated week after week amid denunciations of individuals who supply the "lay press" with information.

The Hospital Reform Association has had another meeting and will address the managers of hospitals and then the public. The first efforts of the new organization will be directed against the abuse of the outpatient system.

Charing Cross Hospital appeals for £100,000.

The Dental Hospital is about to be rebuilt. In fact operations have already begun. When finished the new building will be a great improvement to Leicester Square.

OUR BERLIN LETTER.

(From our Special Correspondent.)

DEATH OF DRS. BAUMANN AND LEWIN—PHYSICIAN AND SCIENTIST—INTERNATIONAL CONGRESS—LEPROSY CONFERENCE—ROENTGEN RAYS IN INTERNAL DISEASES—MEDICAL EXAMINATIONS AND THE OTOLOGISTS—FRÄNKEL'S BIRTHDAY.

BERLIN, December 18, 1896.

Two meritorious workers in the cause of science are numbered no more among the living—Professor Baumann, late of Freiburg, and Prof. G. Lewin, late of Berlin. Baumann, that untiring worker in physiological chemistry, to whom medical science owes the discovery of thyroidin, has been cut off in the midst of his labors. Through his great discovery, the functions of the thyroid gland were first properly understood, and we can now explain why iodine, used for so long a time empirically in goitre, gave such good results.

Professor Lewin introduced the injection method for the treatment of syphilis as a substitute for inunctions. The medical profession, as well as the patients themselves, soon learned to appreciate the greater convenience of application and the efficacy and rapidity of action following this plan of treatment. Lewin was a man of vast scientific knowledge and experience, not only in the department of syphilology, but also in other branches of medicine. Particularly fruitful were his labors in the department of laryngology. Death overtook him in the midst of his labors. Lewin always interested his listeners at medical meetings, for he had the happy faculty of grasping the most salient points of the subject under discussion, and always drew valuable conclusions from the same.

In contrast to the lives of these two worthy members of the profession, is that of Dr. Volbeding, whose career has been fortunately cut short by a sentence to four years' imprisonment because of fraudulent practices. This man, by skilful newspaper advertising, managed to obtain a yearly income of 400,000 marks. He treated his patients almost exclusively by mail, and had a most original system. Diseases he divided into four great groups. Under the heading "Scrofula," for example, he included almost everything imaginable; so, too, he classed various conditions as cancerous and syphilitic. Each group had its special powders, and he would order one powder from Box I. to be taken early in the forenoon; one from Box II. at noon, and in the evening one from Box III. He warned each patient that "an aggravation of the symp-

toms at the beginning of the treatment is to be regarded as a very hopeful sign." He was absent most of the time, but would inform his clerks by mail what treatment to follow. One does not know whether to be more amazed at the audacity of the man, or the blind stupidity of the public. It is proof that even in this enlightened age, ignorance and superstition are still rife. The most regrettable part of the affair was that this wretch was a practising physician, and boldly maintained and tried to persuade the court that his methods were within the law and were exercised in good faith.

The Berlin physicians are making preparations to take an active part in the international congress to be held at Moscow next year. Efforts are being put forth to have a large representation. Professor Liebreich will probably be chairman of the Berlin local committee, and it is hoped that the name of this honored and learned scientist will prove a stimulus for many to take part. Other local committees have been formed in Hamburg, Dresden, Munich, and other cities, under the auspices of the German general committee. Prominent physicians will act in the capacity of chairmen to these local committees, and will make it their endeavor to have the German representation as numerous as possible.

An international congress of a different nature will be held in Berlin next year; namely the leprosy conference. Prominent workers and authorities in this field of medicine will attend in order to discuss the best means to combat the slow but none the less steady spread of this pest. It is intended to invite the various governments to take part in the conference. Owing to the absence of Koch in South Africa, where he is investigating the cattle plague, it was determined to hold the conference in October instead of in March, as was originally proposed.

The leprosy question is at present awaking great interest in Berlin medical circles. At a recent meeting of the Berliner medicinische Gesellschaft, Dr. Havelburg, of Rio de Janeiro, read a paper upon leprosy in Brazil, and a very lively discussion followed. Lately, several new cases of leprosy have been discovered in the eastern portion of Prussia. These are not new cases, but had escaped observation heretofore. There is no danger of an outbreak of the pestilence. All persons in Prussia who are known to be leprous have been asked and have signified their willingness to enter the proposed home in Memel, thus quieting the fear of a spread of the disease. This will best be appreciated when it is known that compulsory confinement of these cases is not sanctioned by law.

Improved methods in the use and application of the Roentgen rays have resulted in the solution of some important questions in internal medicine. Some time since reports of successful skiagraphy of the heart, lungs, liver, etc., were published. Of extreme interest is the discovery made by Dr. Levy-Dorn, in Berlin, by the employment of rays in a case of asthma. He learned that during an asthmatic attack, one-half of the diaphragm—the right—remained quiet, and that the respiratory movements were maintained through the left half. Dr. Pöch, of Vienna, has succeeded by means of the Roentgen illumination in locating a carpet tack in the lung of a boy. Since swallowing this foreign body, the patient had suffered from severe asthmatic attacks.

Behring's tetanus antitoxin gave proof of its efficacy recently in the case of a horse. The animal was suffering from so severe an attack of tetanus that clinical experience pronounced the case absolutely hopeless. One injection of sixty grams of the antitoxin was given, with the result that in three days the animal was completely restored to health and usefulness. We have thus to all appearances a certain remedy against tetanus.

There is a strong movement under way to make the study of diseases of the ear compulsory at the German universities. The teachers of this specialty have petitioned the "Reichskanzleramt" to the effect that at the State examinations all candidates be required to show sufficient knowledge and skill in this department of medicine for the needs of a general practitioner. The arguments advanced in support are of interest. Figures showing the important part that diseases of the ear play in this country are cited. It is claimed that in Germany there are thirty-eight thousand deaf-mutes whose affliction for the most part was not congenital, but the result of ear affections which, had they been properly treated in time, would certainly have been cured. Twenty-five per cent. of school children and thirty-three per cent. of adults hear with difficulty. In the case of children this interferes with mental development, and in the case of adults naturally makes the gaining of a livelihood more difficult. Suppurative processes in the ear are the cause of one death in one hundred and fifty-eight. These naturally are points to be considered with some seriousness, and no doubt the application of the otologists will be granted. Recently the studies of ophthalmology, psychiatry, and hygiene were made compulsory upon similar grounds.

In concluding this letter, it is proper to make mention of another celebrated medical worker. Prof. B. Fränkel, who easily ranks as the highest German authority in laryngology, is about to celebrate his sixtieth birthday. His services to science are so well known to the medical world that it would be superfluous to speak of them now.

THE LEGAL RESPONSIBILITY OF EPILEPTICS.

To the Editor of the Medical Record.

Sir: The acquittal, on the basis of irresponsibility, of Maria Barberi, the Italian girl recently tried in New York City for the murder of her lover, will doubtless be regarded as a just verdict by the student of epilepsy who has known the disease sufficiently to enable him to understand the mental infirmity and curious mental phenomena to which all epileptics are susceptible, and from which a great majority of them suffer from time to time.

But the acquittal of this girl on the ground of irresponsibility seems to us to open up a perplexing problem, and the question at once presents itself: If she was not responsible at the moment the deed of murder for which she was tried was committed, and if she was known to have been a sufferer from epilepsy at other times, during which times she was likewise in an irresponsible condition, why is it that some means were not taken for the removal from society of so dangerous an agent?

A curious legal point is involved just here.

Provision is made by law for the removal from society of an insane person who may be regarded as dangerous, but, so far as we are aware, legal authority does not exist by which an epileptic can be deprived of his freedom, even after he has committed the greatest of crimes, because he is irresponsible instead of insane—a dangerous distinction without a difference, and one likely to work serious mischief.

Epilepsy, instead of insanity, may now become the popular plea on which to base a defence before a court of law of a person charged with crime.

Being insane, the offender cannot be convicted, but after the trial he is not turned back into society and is confined in such a manner as to insure the public

peace. The only factor in insanity, so far as the necessity for removing the lunatic from society and putting him under physical restraint is concerned, is that of irresponsibility, and this is the same dangerous screw that we find loose in the case of the epileptic.

I do not assert positively that an irresponsible epileptic cannot be deprived, through legal processes, of his liberty, but the liberating of Maria Barberi by the court, immediately after the verdict of "not guilty" was rendered, would seem to imply the absence of any such power on the part of the court.

When we consider the great number of epileptics there are at large, careful statistics placing the number at one in every five hundred of the population, we can readily understand the far-reaching meaning that the outcome of this case is liable to have, and it may be that we shall shortly see legal steps taken for the forcible removal from society of all epileptics.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending December 26, 1896:

	Cases.	Deaths.
Tuberculosis	161	100
Typhoid fever	37	7
Scarlet fever	112	5
Cerebro-spinal meningitis	0	1
Measles	121	7
Diphtheria	190	28
Laryngeal diphtheria (croup)	9	0
Chicken-pox	5	0

Billroth's Advice to a Young Man Intending to Study Medicine.—A correspondent of the *Boston Medical and Surgical Journal* has published a letter addressed by Billroth to an intimate friend, from which we extract the following: "You tell me of the tribulations of the landed proprietor, his subjection to wind, weather, fire, and the like; well, I have no intention of discouraging you or Robert, but the doctor does not lie altogether on a bed of roses. Competition grows constantly more fierce; in the beginning things generally come hard. As a student one has the pleasure of obtaining something of a glimpse into the workings of nature, as well as the diseases which assail humanity. The state of entire satisfaction which ensues on the passing the examinations is gradually undermined by the discovery that our knowledge is but fragmentary; that in those cases where we would most gladly render assistance we often fail of doing so; often, too, are we harassed by doubts as to the proper course to pursue. Unless one is willing to pass through the world in a state of chronic perturbation, one must rest content with doing his duty to the best of his knowledge and belief. A man's greatest blessings are then met with in the shape of a placid and loving wife and undisturbed domestic happiness. Hardly, however, have you reached your home prepared to enjoy these pleasures, when there comes a knock on the door, and duty calls you out again into the cold and stormy night. Few are the joys of the physician. Here and there true loyalty on the part of his patients, emphasized occasionally, although perhaps seldom, by a material token, infrequent gratitude for the most absolute devotion to duty, nay, even for personal sacrifice: joy over a completed cure: the consciousness of having done one's utmost—these are ordinarily the highest satisfactions the physician can attain. You think, perchance, that I paint the picture in too gloomy colors: but when twenty years have gone by and these lines fall into Robert's hand, he will perhaps say that I was right. If once he has a true vocation for medicine, he need not take this into much account. You wish me to write you plainly and in detail. Do not fear lest I continue in this strain: the worst has been said, and, after all, the state of things here is not much worse than one finds in other walks of life. What special quality must one possess in order to be a good physician? My colleague here, Nothnagel, whose work on diseases of the nervous system will at some later day be appreciated by Robert, when inaugurated professor of the house clinic here, said, among other things in his address, 'Only a good man can be a good physician,' and I too share this opinion: it is the supreme regulator of the inner, as well as of the outer effect of the physician's actions. To the phrase 'good man' I would like to add the words 'well brought up,' that is, in a family the existence of which is permeated by a spirit of charity toward all mankind. This condition is fulfilled in the case of your Robert. He must be actuated by an uncontrollable impulse to help other unhappy creatures, at first implanted in him at his birth and well developed; while cultivated feeling and the experience of life have later led him through reflection to the conviction that, however eagerly the man of moral training may chase after happiness, he will ultimately find true happiness to lie in making others happy to the extent of his ability. In this direction alone dare he cultivate egotism, I mean make himself happy, and as much so as possible. In so far as this originates in his moral training, it will be a never-failing source of self-purification, a means of strengthening the sense of duty, a reinforcement of his own moral nature. Should misfortune overwhelm him, he will find that, in assisting others who are even more unfortunate than himself, he has gained comfort as well as the strength requisite for pressing on in the race. To enable the physician to spend himself freely, he must have accumulated a rich fund of knowledge. And in possessing such a treasure the physician enjoys the special privilege of seeing it increase directly in proportion to the lavishness with which it is spent. Activity in the practice of medicine leads to increase in experience, development of judgment, impels us to supply the deficiencies in our knowledge, enables us to follow the progress of the art of medicine, which itself results from the progress of science. A physician who gives himself up to critical, unprejudiced observation sees his own stock of experience and knowledge increase in the very dispensing of it for the relief of others—always provided that he is a good man, with a strong sense of duty, has a sound understanding, and takes delight in work and in his calling."

Psittacose.—This disease, named in honor of the bird which was considered responsible for its occurrence for the first time in Europe, in 1892, has been reviewed in an article which takes up nearly the whole of No. 111 of the *Gazette des Hôpitaux*. It will be remembered that in 1891 two Frenchmen brought into Paris two hundred parrots bought in Buenos Ayres. Three hundred of the original lot purchased had died *en route*. The surviving birds were divided into two lots and slowly disposed of from two remotely separated parts of the city. From one focus of infection twenty-two persons became sick and six died. From the other, twenty cases of sickness occurred and eight of them proved fatal. Professor Nocard found, as he supposed, the specific agent of the epidemic,

which Peter characterized as "typhus of parrots." The writer of the present article, Dr. Descazals, reports an epidemic observed by himself, affecting five persons and resulting in one death. A parrot had in this instance also been bought a short time before and had died, with symptoms of diarrhœa, hebetude, and continual somnolence. An individual infected by the pest would seem capable of transmitting the disease to others. It is often distinguished with difficulty from certain other typhoid states, but the onset is often marked by local manifestations about the mouth, especially in persons who have allowed their pet, particularly while ailing, to take food from their own lips, as is so often the custom. There would seem to be a light form, an adynamic, a nervous, and a pulmonary form. It offers many points of resemblance to grippe and is likely to be confounded with typhoid. Treatment is largely symptomatic. Prophylaxis requires us to place the possessors of such pets upon their guard, especially in relation to feeding from the mouth, and particularly when the bird is sick.

Correction.—In the issue of November 21st, page 765, the dose of trional should evidently read grams instead of grains. Upon page 800 the quantity of mercuric chloride in Dr. Neilsen's prescription was presumably meant to be from a quarter to half a grain.

Is it Practising Medicine for the Vermont healer to allow his manager to advertise his powers by reading-notices in the public press, and to accept fees for undertaking to cure disease?

A New Test for Albumin.—Reagents for the detection of albumin in the urine must be colorless and must reveal the presence of albumin even when the amount is too small for quantitative estimation. Dr. Jolles has published a new and delicate test, consisting of:

Chloride of mercury	10 gm.
Succinic acid	20 "
Common salt	10 "
Distilled water	500 "

In the process of testing, 4 c.c. of the filtered urine are mixed with 1 c.c. of acetic acid, and 4 c.c. of the above reagent are added with shaking. In a second glass similar quantities of urine and acetic acid are mixed with pure water instead of with the reagent. This test yields a cloudiness of albumin in cases in which the ordinary tests fail to give any result at all.—*The Lancet.*

Congress of Natural Sciences.—At the recent congress in Berlin the meetings were devoted chiefly to recent discoveries and their results. In the opening address, Dr. Schmidt said the discoveries of Koch, Behring, and Roentgen could scarcely be open to doubt, while scarcely a hundred years ago great truths now recognized and accepted were looked upon as impossibilities or as the outcome of disordered brain work. A hundred years hence we shall still be able to see the bones of the living body, the pulsations of the beating heart, the movements of the diaphragm. We may then know, too, that oxygen and carbon are not single but compound bodies. We may learn to decompose such bodies into their component parts. We shall learn to prepare food stuffs, perhaps not from stone, but certainly from wood. Professor Flechsig, of Leipsic, spoke of the localization of spiritual and sensory processes in the brain, especially those of circulation. He expressed himself to the effect that our methods were so advanced that we could now localize in the human being, though by a somewhat complicated process, an increased number of sensory centres, which previously we were enabled to do only with great difficulty on animals. Without doubt we can accept it as a fact that there are a centre for movement of the muscles of the skin and a centre for the circulation of the skin. There is a centre for the smell, and there are many, many more. Professor Edinger, who is well known, spoke upon experiments on the brain. Professor Ewald referred to the relation of the motor cortex of the brain and to the labyrinth of the ear. Professor Buchner spoke about the relation of hygiene and biology, and put forward a great many new ideas. Hygiene, he says, diminishes mortality. This has a great many disadvantages. For instance, many individuals are artificially kept living and in the struggle for existence exert an unfavorable influence upon the community. Buchner advises compulsory physical exercises for early youth. Professor Thiem spoke upon a most important subject in connection with accident insurance, and mentioned in this speech the origin of traumatic tabes dorsalis. He is not of the opinion that this is produced by an injury, but he is almost positive that this dreadful disease is for a long time in the human system without the patient or the physician being aware of its existence. By an injury, he says, its manifestations can be produced all of a sudden. It may be awakened, so to speak, from its sleep, and then produce violent and characteristic symptoms. These naturally are cases which are of the utmost importance from an insurance standpoint. The accident cannot be considered as the cause of the disease, since it was present a long time before the accident happened. The accident is only the originator to the extent of bringing to light a condition which existed, we do not know how long, in the system. Fortunately for the patient, the opinion of the judge is usually favorable to his side, because the hastening of the disease process justifies the patient in receiving an indemnity. The speaker referred to the case of a railroad conductor who for years had latent tabes and who had always followed his occupation, until finally a fracture of his lower leg caused the disease suddenly to break out. Dr. Rosenberg spoke about the application of formaldehyde as a remedy. He applied a sixty-per-cent. alcoholic solution for preserving and sterilization; also in the treatment of infectious diseases. The substance is put upon plates and allowed to evaporate slowly. By the addition of menthol the irritability of the formaldehyde gas is reduced to a minimum, and it is supposed to have a very soothing influence upon the mucous membranes of the digestive organs. With this substance a perfection is reached in disinfecting rooms such as we have never had nor heard of before. As affecting the bacilli of glanders and their process it must certainly be considered as having a special value. This remedy seems to be applicable in croup, tuberculosis, diphtheria, etc. Against the application of formaldehyde in the human being a great many objections have been raised on account of its poisonous properties. Further to receive mention are the lectures of Boas upon asthma dyspepticum, those of Abbu upon the influence of milk as a disinfectant in the digestive tract, and the lecture of Professor Born, who spoke about artificially prepared double beings. He had succeeded with larvæ of the green-water frog, the Latin name of which is *Rana esculenta*, in causing them to grow together by scratching them in various places and tying them together with the irritated surface in contact. In this way he had produced a double animal of different shape. It is impossible here to mention the five hundred and fourteen papers read, far less to speak about them. The closing of the congress was marked by a visit to the serum laboratory in Hochst by special train. Professor Behring received his guests personally, and in an address explained the processes carried out in the preparation of serum.

SOME PLAIN RULES FOR OPERATING IN APPENDICITIS.[1]

By GEORGE F. SHRADY, M.D.,

NEW YORK.

In presenting a subject having the above title, I am well aware that some apology is due to members who have settled the questions long ago in their own minds; but that the mass of the profession, in view of recent controversies, is by no means in the same position is perhaps a reasonable excuse for supposing that an attempt to establish a conservative clinical standard between extreme points at issue may not be in vain. That great good has resulted from the frequent discussions on the subject is manifest by the remarkable successes that have attended judicious operative procedure, by the steady advances in the study of the pathology of the affection, and by a widespread knowledge of its symptomatology. On all these points there is scarcely any difference of opinion; the really debatable question is when an operation is actually necessary in doubtful cases.

In former times, when every case was operated upon, there was but one answer. Now, however, the pendulum has swung so much the other way that we are in danger of the other extreme of indiscretion. It is for the sake of reconciling opposite views, on the basis of the significance of certain clinical phenomena as applied to certain pathological conditions, that we may profitably compare individual experiences and arrive at rational conclusions. It appears evident that enough has already been done in this direction to make it possible to formulate some rules from leading symptoms, which may in the majority of cases settle the more common differences of opinion regarding the real necessities for operation. With such an end in view, an attempt will be made to analyze the significance of such symptoms and to estimate their real bearing upon the ultimate decision. The object is rather to furnish points for a discussion, for the benefit of such as may need the information thereby obtained, than to attempt any elaborate paper on the wider and more general aspects of the question.

In order to approach the subject in a natural and simple way, I have undertaken to study the detail histories of a large number of reported cases, noting in each the relative constancy of the leading symptoms of localized pain, fever, tumor, and pulse rate.

Three years ago, in an article before this society on the diagnosis of appendicitis, I attempted incidentally to lay down certain rules for guidance, with the view of simplifying the methods of reasoning in given cases, based upon the relation of the leading symptoms to pathological conditions. Since then a more extended experience has in the main confirmed the reliability of most of these observations, and modified or qualified that of others.

Taking the judiciously conservative ground to operate or not to operate as the occasion demands, we may appeal impartially to the common sense of the general practitioner, who is usually the first to advise in the premises. He is always prompt in making his diagnosis, but not equally so in appreciating the elements in the danger of delay, which a more careful watching of the case may avert. In private practice the responsibility of advising any operation is always attended with difficulty when the reasons for such a course are not well fixed. In remote districts expert surgical advice is not always readily obtainable, save at considerable expense, and the country practitioner, especially, is oftentimes in doubt as to the expediency of suggesting surgical consultation in what may prove to be a simple and uncomplicated case. The latter are numerous and frequent enough to deserve calm consideration. They demonstrate in the practice of every one that there is such a thing as safe conservatism, and that patients recover without operation and remain perfectly well for long and indefinite periods. Thus, while every case should be watched and studied for dangerous symptoms, there is something else to be thought of than an immediate operation.

As a proper starting-point for the consideration of the particular subject of these remarks, it may be said that what localized pain is to a diagnosis, so is the increased pulse rate to operation. Of all the symptoms indicating danger that of the condition of the pulse is the most important. This is by no means a new observation, but one which is either not sufficiently enforced or not properly appreciated. I have been led to believe, from personal observation in a goodly number of cases, operative and otherwise, that this is the main and oftentimes the only guide to operative interference. Other signs may be wanting, but this seldom fails. A "snappy" inflammatory pulse, continuously accelerated or increasing in frequency, is almost always an indication for operation. This always shows an actively progressive pathological condition.

The next important consideration is that of the character, localization, and persistence or increase of pain. Localized pain at McBurney's point, although an essential element for diagnosis, is of secondary account as compared with the pulse in estimating the indications for operation. While it should always be present to a greater or less degree in all cases, its progressive intensity, which means so much, is not always manifest, even in the worst cases. Usually, however, the two essential elements of the pain symptom, with distinct localization and progressive intensity, correspond with the increase of frequency of the pulse. The sudden increase of pain is an indication of serious mischief, and when present outweighs that of mere temperature elevation in the argument for immediate operation. It is a leading symptom in perforation, in the so-called fulminating cases, and, save in exceptional cases, is always attended with symptoms of severe shock, usually with preliminary chill and generally with rapidly increased temperature.

The temperature in appendicitis is never very high; as a rule, the average is about 102° F. Without the symptoms previously stated, there may be a reasonable doubt as to the correctness of a diagnosis. By itself,

[1] Paper read before the Practitioners' Society of New York, November 6, 1896.

then, it means very little in our present estimate, but, associated with the other phenomena named, it makes assurance doubly sure. In fact, the increase of the three elements in the order of their importance, pulse rate first, pain second, and temperature last, constitute the cardinal indications for operation in every case; and, contrariwise, a decrease along the same lines, but more especially in the pain and pulse rate, means judicious waiting and safe conservatism. The actual number of pulse beats is not of so much account as their tendency to increase, although the rule of Willy Meyer, to operate when they reach from 116 to 120, is generally a trustworthy one, as I have proved in many instances.

While I desire to emphasize these points as the really essential ones upon which quite positive opinions may be based, we are not to lose sight of incidental circumstances which may be considered in the way of corroborating or of modifying final conclusions. Aside from the symptoms already mentioned, the general gravity of a case has a direct relation to severity and suddenness of the attack, but more particularly to the associated condition of prostration of the patient. He has what is graphically called "a very sick look"—always an ominous and anxious symptom, and almost invariably accompanying one or more of the cardinal signs of danger.

In the foregoing *résumé* we have taken into account only those symptoms usually noticed in the majority of cases which from the very nature of the disease require careful study and accurate interpretation.

Just here it may be stated that there is usually no necessity for hurry in arriving at conclusions. Except in the fulminating cases there is always opportunity offered for noting the course of the disease. The initiative symptoms are generally very pronounced and exaggerated. A snap diagnosis is always unsafe under the circumstances. After the explosion of the primary attack there is a comparative retrogressive lull, and then comes at the end of from twenty-four to thirty-six hours, or longer, the important time for the study of what can then be demonstrated as the progressive signs of trouble.

The fulminating cases, however, in which immediate perforation occurs, admit of no argument as to the necessity of prompt and radical measures. Nor is there any danger of misunderstanding the significance of their symptoms. The sudden agonizing pain, first localized and then becoming general, the rapid thready pulse, the pinched face, hurried grunting respiration, increased temperature, and abdominal distention leave no doubt in the mind of the most casual observer. In the majority of these cases the increase of the pulse rate often anticipates that of pain and temperature.

While every one knows that all cases of appendicitis require the most constant and careful watching until actual recovery takes place, that we are never out of danger until all symptoms of the disease have disappeared, it is also true that there is no necessity of becoming alarmed without cause, or becoming accessory to the patient's death by an overanxiety to operate. It is with the view of enabling the practitioner to take a common-sense view of the question that this effort to formulate certain rules is attempted, in the hope that by being forewarned he can be safely ready and be the better qualified to study indications with becoming calmness, and not be forced into unwarrantable exploratory operations against the dictates of his better judgment. This may sound like a surgical heresy, but we must admit, nevertheless, that we can always afford to wait for emergencies rather than be too eager to anticipate what may never happen.

I cannot help believing that, with a laudable attempt at warning the family practitioner against neglect of appendicitis cases, there has been an unnecessary scare about the whole matter. We have very grave cases, it is true, but the majority are not so bad as they are oftentimes pictured. In the present aspect of the question, it requires much more moral courage in a given case to advise against the operation than to perform it.

The appearance of a tender swelling from the third to the seventh day of course adds to the gravity of the case. This means that pus is forming and limiting adhesions are appearing. In the face of the surgical rule to evacuate abscesses, the question as to the time when this should be done with the greatest safety is still a debatable one. In a rapidly progressive case the danger of rupture of the abscess wall is very great; on the other hand, premature interference with the protecting adhesions by inexperienced operators precipitates the very accident we desire to avoid. In every case of doubt the risk is equally divided. It becomes a question of judgment in every individual instance, founded on the accurate interpretation of the clinical phenomena. If the initiatory symptoms show a tendency to subside, it is good surgery to wait until the circumvallation is sufficiently firm. In the end, instead of a laparotomy, we have nothing more dangerous than the evacuation of an isolated abscess. The greater danger in the acute cases exists before adhesions have time to form. As a rule, the fulminating cases appear during this period. In my experience the breaking down of adhesions is a comparatively rare occurrence compared with the formation of a distinctly limited abscess.

Now as to recurrent cases. I am well aware that it is claimed by many leading authorities that the appendix when once inflamed is always a diseased organ. This assumption would make it impossible for any case, mild though it be and unattended by severe symptoms, to recover entirely without an operation. We all know that this is not the case—that patients do recover after a first attack and remain well for an indefinite period. In spite of the pathological theories of the day, there is no good reason why this should not be so. The inflammation does not necessarily result in structural changes. Admitting the great liability of such occurrences due to the peculiar anatomical formation of the appendix, they can never be proven unless subsequent localized pain or circumscribed swelling persists, or a distinct rehearsal of former acute symptoms demonstrates the existence of fixed adhesions and the inability of the appendix properly to rid itself of its imprisoned secretions.

Logically viewed, it would appear to be a safely conservative course, under the circumstances named, to steer between the certainty of a diagnosis and a minimum amount of adhesions. It is the difference between actually seeing the game and in firing with a chance shot. The trouble has been that the argument for or against operation in these cases has developed in the expression of extremely opposite views. With one set of men appendicitis means operation always and under all circumstances; with another, simple medication and dangerous procrastination alike offset sound judgment. It is in the direction of reconciling these diametrically opposite views that a conservative opinion is offered.

In attempting to simplify the leading facts upon which good judgment may be based we do not lose sight of the fact that there are exceptions to all the points named—that patients with a temperature and pulse rate almost if not quite normal, and with scarcely any pain, rapidly go to the bad; that the apparently mild cases in the beginning turn out the worst in the end. Few, however, do this without some preliminary warning. They are what may be called irregular cases. Their defiance of ordinary rules makes them suspicious ones. One or other of the leading

or casual symptoms assume sudden and significant prominence. There is a something in the air that makes us think of a weather breeder. These cases are always taken into account in laying down general rules. They cannot be ignored, but fortunately they are not of such frequent occurrence as some would lead us to suppose.

In order, then, to summarize the points upon which a discussion may be invited, the following propositions are offered:

1. The continuously frequent or progressively accelerated pulse rate is of itself a prime indication for operation.

2. Pain, localized and progressive, is a valuable associated condition. When pain is sudden, severe, and progressive, and accompanied with chill, it means perforation or abscess rupture and immediate operation.

3. Increase of temperature is third in importance, but when associated with one or more of the previous symptoms, and more especially with increase of pulse rate, it makes immediate operation a foregone conclusion.

4. The gradual subsidence of the three cardinal symptoms—pulse rate, pain, and temperature—is a legitimate reason for postponing immediate operative interference.

5. In cases of abscess it is generally safer, while watching for urgent indications, to wait until adhesions have formed a sufficiently protective wall.

6. In cases of recovery after mild attacks and without operation we are never sure of recurrence until the latter takes place, when the operation can be done soon enough, and, all other circumstances being equal, preferably in the interval of a succeeding attack and when the tissues are not in an inflamed condition.

8 East Sixty-Sixth Street.

SIMPLE MELANCHOLIA AND ITS TREATMENT.

By H. E. ALLISON, M.D.,

SUPERINTENDENT MATTEAWAN STATE HOSPITAL, NEW YORK.

The beginnings of melancholia, as a rule, are quite gradual. It is usually a disease of insidious and slow growth. Often the condition of mental depression is so slight and the bodily symptoms are apparently so trivial, that physicians frequently are not inclined to attach much importance to them. It is a disease which arises from a lowering of the physical and mental forces, is accompanied by depression of spirits, and is attended by nervous exhaustion. A condition of neurasthenia in itself does not necessarily lead to insanity, yet the latter is often accompanied by it.

There are various degrees of mental depression: first, what is known as the simple or mild form of melancholia; second, the form attended with stupor, or melancholia cum stupore; and lastly, the agitated or frenzied variety. They are simply grades of the same disease; and, as the mental reduction becomes more pronounced, the more severe is the type of melancholia that presents itself. It is the first variety—namely, simple melancholia—that more commonly comes under the notice of the general practitioner, and it is a very prevalent form of mental disease. These slight or mild exhibitions of melancholia are manifestations of prime importance, for it is by the successful combating of them that an attack of severity may be warded off and the patient's health and reason preserved. In all these forms the chief mental factor that is noticeable is the predominance of self.

[1] Read before the Newburg Bay Medical Society, Newburg, N. Y., November 10, 1896.

This feature is ordinarily termed egoism, and is quite distinct from what we understand by egotism or self-conceit. The patient in melancholia is self-conscious, and lacks the buoyancy and freshness and reliance that are attendant upon normal health. There are usually no definite delusions accompanying this state, and the patient attends to business or work, sensible, however, that it has become more of a burden to him and that he is unable to fix his attention upon it as formerly. He has lost the power of concentrated attention and consecutive thought. His ideas are apt to be confused, and the strength of mental application is gone. As a rule, such persons shun society. They do not mingle with men more than their daily duties require of them, and have a strong aversion often to meet those whom they feel to be really their friends. They are morbidly self-conscious and sensitive, and reach at last a state of great indifference to all that once served as exercise, recreation, or pleasure. There are a difficulty in paying proper attention to business and a lack of association of ideas, and the patient's mind is given up to introspection and gloom. There are very many people who suffer from periodic or occasional attacks of this nature, whose will power is sufficient to keep them up and who present their ordinary aspect to the world, but who confide to their physician what they dread may come to public knowledge and which they are anxious to conceal. It is these cases which can be most successfully treated, and the results of which are often most satisfactory.

While neurasthenia is held to be a disease distinct from insanity, yet the two are closely allied, and many cases of neurasthenia are simply cases of mild melancholia. There are a condition of mental weakness or depression, with intense egoism or self-introspection, and a failure of thought and effort; as one young lady expressed herself, she could get her thoughts together, but she could not connect them and the effort made her weary. Many business men are afflicted in this manner. They are annoyed and made irritable by company; they are afraid to go on the street or to meet people socially. This state is attended by mental depression and the concomitant feelings of physical weakness and constant fatigue. The patient is unable to overcome ideas which dominate his mind, and yet which he feels are unreasonable and absurd. He often comes to the physician simply for the reassurance which he receives and which is an aid to him. It is an error to treat such cases with rebuffs or ridicule, or as of little consequence. They should receive the serious attention and the helpfulness which their condition requires. It is surprising often to what lengths the habit of self-analysis is carried, and with what importance the smallest affairs are invested. To his friends, and ofttimes to his physician, his complaints are so absurdly small as to be treated with impatience or indifference. What patients of this character need is the moral support accorded them by another, in whom they feel a confidence and from whose words they experience a sense of strength and relief. Most physicians who successfully treat such cases do so because of the confidence they inspire and of the co-operation they are able to obtain from the patient himself. This may with truth be said of many diseases. The successful physician is the one that can obtain the confidence of his patient.

An important prerequisite to treatment is to place the disease upon a physical basis in the patient's own estimation of himself, and to divest it of its mental character. If the patient can be made to think that he has some tangible foe to combat, he will feel much relieved in mind. If he is told that his liver, his digestion, his intestinal functions are at fault, as they usually are, and that his mind is depressed by an impoverished circulation due to toxic agencies in his

blood, he will feel that he has something to hope for in the way of eventual relief. Suicidal impulses may occur in some cases, but in simple melancholia the patient usually retains enough self-control effectually to guard against the act itself. His greatest fear is that he may become insane, and he hesitates even to express his fear, lest the expression of his thought may become a father to the fact.

The patient's confidence is the important factor, then, to be gained, for without it no successful method of treatment is likely to prevail. Patients are usually free from delusions in the early stages of melancholia, though they may have exaggerated and it might be said false ideas of their own mental and physical condition. Still, such ideas are simply errors of judgment, amenable to reason, and out of which, by careful attention to their cases, they can be educated, such mental training going hand in hand with therapeutic treatment. We all recognize the powerful influence which the mind has upon the body, and instances are familiar to us all. Sudden fright, the shock of unexpected bad news, the yearnings of homesickness, the stress and strain of financial embarrassments and of grief, affect both mind and body, often destroy the appetite, hinder digestion, drive away sleep, and impair the health. Sudden shock may cause syncope or even death. Homesickness may so depress the mind and health as to result fatally; anxiety, care, and responsibility may render the night sleepless, and sudden alarms soon after or during the hour of dining may stop digestion and render the ingested food really a foreign body. These facts are not known to the public, or, if known, are not appreciated by them. Let the melancholiac know that there is a physical basis to his ills, and you drive away the demon of vague and indefinable fear and gain thereby a most helpful mental effect. How much, then, to be valued are the services of the family physician who is sympathetic, helpful, encouraging, and strong to sustain the despondent and to lighten the burdens of the incipient melancholiac! I believe this can be attained by ascertaining, if possible, the real basis of the attack of melancholia itself, or at least by finding out some of the actual physical causes which do exist, and explaining to the patient as clearly as possible the true state of his bodily health and detailing the *rationale* of the general plan of treatment which you propose to follow. As a rule, patients are benefited by knowing that their mental condition is probably dependent upon some physical cause, which is removable by treatment. In my experience, the gloom of a patient's mind is largely due to the feeling that his trouble is entirely mental, and he is apt to regard his other ills as secondary and unimportant, in which view he is altogether wrong, although he is often sustained in it by his family and friends.

The derivation of the word melancholia throws some light upon its most common etiology. The two Greek words, *melas*=black, and *chole*=bile, while not accepted in their original application and significance in the sense of meaning that melancholia is actually due to bile in the blood, yet disturbances of the digestive organs, the intestinal canal, and the liver have a most important relation to the production of the disease. In many cases there is a strong hereditary tendency, but its actual onset is due to some special exciting cause that in very many cases is removable by proper prophylaxis and treatment. I have known several instances in which insanity prevailed largely in the family history, yet in which it has been warded off by attention to simple measures of hygiene and seasonable treatment. Of course, if the patient is suffering from special disease, such as rheumatism, hemorrhoids, neuralgia, or syphilis, or from any physical defect, such as eye strain, an old stricture, or any one of many ills, the attention of the physician will be directed thereto and to its appropriate treatment; but most cases of simple melancholia are idiopathic, or are so apparently.

You will find in these cases that there is, as a rule, some disturbance of the digestive system. The patient may suffer from some form of dyspepsia, and almost always does suffer from constipation. Constipation may be quite certainly counted upon, and with it hemorrhoids. There are sometimes much flatulence, a sense of weight and distress after meals, often ill-defined feelings of discomfort or vague pains in the abdominal regions. These conditions are relieved somewhat by gaseous eructations, sometimes accompanied with acrid or bland fluids, but more commonly free from them. The belching of gas often gives a sense of relief, which is temporary. While stomachic disturbances are not the most prominent and are not always present, there is, as we have said, almost universally a state of chronic constipation. It is to this condition that attention has been more or less attracted of late, through the theory that many forms of mental disease, not only in their initial stages but also in recurrent and periodic forms, are due to intestinal infection or autotoxis. It is reasonable to ascribe also other forms of mental disease to this source of toxic infection. In no form is this more true than in melancholia. The intestinal contents are retained, and by being absorbed poison the circulation by toxic agents that seem to work directly upon the nervous system; and not only this, but digestion itself is so imperfectly performed that the food is not assimilated and does not nourish the body. Melancholiacs, as a rule, are reduced in weight and are often emaciated. The evacuations from the bowels are scanty and frequently suppressed for days. The patient's appetite often is poor, and the reason is frequently given as an excuse for constipation that the patient eats nothing and a fæcal movement is not deemed necessary. The evacuations, when they do take place, are often small cylinders or lumpy, and are usually dark or occasionally extremely light in color, and often extremely offensive. This condition of retained fæces in the intestinal canal often leads to what is termed copræmia or fæcal autotoxis.

The chief duty in all cases of this character is to pay attention to the digestion and to the atonic state of the bowels. It is not well to prescribe violent cathartics, but to give in daily doses small amounts of buckthorn or cascara. The pill of aloin, strychnine, and belladonna, continued day after day, is a most excellent remedy. An occasional dose of calomel is also efficacious, in the form of small doses of the triturates in one-half or one-tenth grains, frequently repeated. It acts as a laxative and, in the opinion of many, as an intestinal antiseptic as well. All of these patients should be taught that one of the most serviceable methods to promote regularity of the bowels is to take some special time of the day for the performance of this duty. The habit of defecation at a certain hour can be acquired, and it is extremely important that these people should be taught to acquire it. They should be made to persevere for a long time, even though no apparent benefits ensue. The Saratoga mineral waters and some of the stronger aperient waters are useful when taken regularly as an aid to this result. The appetite of melancholiacs is not often good. They need more than the usual amount of food, even though they are not actively exercising. One of the most encouraging things in the treatment of these cases is the gain in weight which indicates improvement. This is one of the criteria of successful treatment, and is often the first evidence of returning health. It is well to weigh your patients from time to time. In certain cases of obstinate dyspepsia

it is sometimes necessary to wash out the stomach by lavage before meals, but simple aids to digestion will ordinarily be sufficient. The drinking of hot water sometimes serves a good purpose. Reliable preparations of pepsin, in ten or fifteen grain doses, or other digestive ferments, are of service. Nitromuriatic acid or hydrochloric acid is a useful remedy for continuous use. The subgallate of bismuth is an efficient agent in the disease, and may be given in doses of five or ten grains. It exercises a mild antiseptic influence upon the digestive tract. Salol, in from two to five grain doses, I have found to produce good results. Naphthalin, in from one to three grains, and its allied products, have been used also for the purpose of local intestinal antisepsis. It will be found necessary to vary your remedies from time to time with notional patients. This can frequently be done, seemingly, without any actual change of medication, or a slight one; for the melancholiac is a variable patient, without much enthusiasm, and his confidence in drugs soon wanes unless reinforced by an apparent change. Cod-liver oil, a most nourishing diet, with plenty of butter, eggs, milk, and cream are indicated. The important element in treatment is to get the patient's bowels in condition and give him good digestion, and then or simultaneously insure the ingestion of large amounts of nourishing food. Phthisis, though not often, yet is sometimes attended with melancholia, and in this disease gain of weight brings with it corresponding cheerfulness of spirits. With the arrest of the disease, the melancholia usually disappears. In all these cases, of course, attention should be paid to the patient's clothing, and warm woollen underclothing and warm stockings should be worn, and the patient kept comfortably and hygienically clad in all weathers and under all conditions, and he should take only moderate and pleasant exercise.

Sleeplessness is often a factor that is difficult to treat. When the true cause of the patient's worry can be discovered, its removal, or, if that cannot be effected, strong judicious counsel on the part of the physician, may often do much to ameliorate the condition by encouraging the despondent patient and giving him moral support. Hyoscine in small doses in these initiatory stages is often of service. A single dose of chloral, or chloral and bromide combined, in doses of ten to fifteen grains each, often act well. The practice of giving these patients hypnotics and sedatives frequently through the day is, as a rule, bad. In many cases it intensifies the mental symptoms, and often the complete stoppage of all medication in cases of overdrugging will be productive of very apparent benefit to the patient. A glass of dry wine, or an eggnog, or a full meal even, will dispose the patient to sleep. Sulfonal or trional in these cases acts well if given in divided doses, the first about three hours before bedtime, and the second portion shortly before retiring. Opium at times acts well, but the after-effects and the constipation produced are unfavorable factors in its use. The two important indications are to eliminate the intestinal self-infection and thus purify the blood from toxic agents, and at the same time do away with the starvation of the tissues from unassimilated and insufficient food. The symptoms, as a rule, will disappear without other special treatment if these matters are successfully combated.

The question of intestinal putrefaction and infection as a cause of acute insanities has for some time been recognized. From time to time writers have called attention to this matter, and its importance has impressed itself upon every asylum physician. The tendency of late years has been turned to the germ theory as productive of disease. It is probable that the septic products of active bacterial growth in the ill-digested and decomposed contents of the intestinal canal may be absorbed as a toxic agent in the circulation and result in the various forms of melancholia. Germs themselves may gain entrance to the blood, and it is a theory for our consideration whether many forms of mental disturbance may not be manifestations of bacterial activity. Certainly, treatment directed to the relief of indigestion when present, and of constipation with its attendant evils, which is an invariable accompaniment, and the administration of remedies which shall render the intestinal canal in some degree aseptic, has met with the best possible results in my own experience. This course renders the giving of large amounts of nourishing food possible, and leads to a gain in fat and blood and in weight, and certainly promotes a cure. These cases of moderate melancholia are most hopeful; the treatment is usually somewhat prolonged, and as the patients are often intelligent and, in the event of recovery, appreciative, most cordial and pleasant friendships are often formed. Your cases are thus rendered most interesting, and at the same time satisfactory.

ON THE RESTRICTION OF MEAT IN THE TREATMENT OF PSORIASIS.[1]

By L. DUNCAN BULKLEY, A.M., M.D.,

PHYSICIAN TO THE NEW YORK SKIN AND CANCER HOSPITAL, ETC.

In spite of much research as to the microscopic anatomy and bacteriology of psoriasis, and notwithstanding frequent studies of its clinical history and reports as to its therapeutics, all must acknowledge that the disease is as yet but little understood, as far as relates to its etiology and to its permanent cure.

Thus far reports in regard to its treatment have been too largely confined to the use of local measures, and but little definite information appears in regard to its constitutional conditions and treatment; and even in text-books but little can be learned as to a course of treatment calculated to permanently cure the disease. We know, of course, that arsenic has been lauded by some as really curative: but I question if many who have seen much of the disease and have watched their patients for a long time find this drug often permanently successful. Indeed, as far as I have been able to interpret literature, the general professional opinion tends rather to the view that psoriasis is an incurable disease, even though the existing eruption may commonly be removed more or less easily by a number of remedies and measures.

All writers certainly agree that psoriasis is exceedingly prone to relapse, and Crocker sums up the prevailing experience by saying: "We know of no means of preventing recurrences, which are almost sure to occur, sooner or later, in at least ninety per cent. of the cases." Surely this is a discouraging outlook, and it behooves the profession to study the underlying causes of the disease with a view to its better treatment.

It has been far too much the tendency to regard all skin diseases as either of purely external origin or else as idiopathic affections of the integument, to the neglect of internal causation. This has undoubtedly been fostered by the readiness with which the skin has been reached by outward applications, and perhaps also by the ease with which it has been subjected to microscopic research of late years. The recent tendency to attribute so much of disease to the local agency of the lower organisms has also contributed toward directing attention from internal causation.

But there are few who will contend that psoriasis is a wholly local disease, either in the line of idiopathic

[1] Read at the Third International Congress of Dermatology, London August 7, 1896.

cell derangement or of external causation; although of late the microbic origin has been claimed by some. The latter, however, seems quite far from proof, and many of the clinical features and relations of the disease point almost conclusively to an internal origin. Among these may be mentioned its common appearance at the developmental period of life, its more or less hereditary character, its periodical recurrence with the change of seasons and food, its remarkable symmetry of location, etc.

When an internal etiology of psoriasis has been more or less acknowledged, various elements have been considered as causative. The older views were expressed under the words constitutional, dyscrasic, diathetic, etc.; and more recent research has looked toward the nervous system for a solution of the problem. At the present writing I do not know if much attention has been given to the possibility of lymphatic derangement as a cause of the disease.

As yet, however, we are greatly in the dark in regard to the real cause of the eruption, and little is positively known as to constitutional states existing in these patients. As a rule, they claim to be, and indeed seem to be in good health, and the eruption appears to be the only element that requires attention. This has far too often led to its consideration and treatment from a local point of view, and to the attempt at its temporary removal only, without endeavoring to reach its constitutional cause. All who are familiar with the disease know only too well how temporary and relatively unsatisfactory this treatment proves to be. The question arises: Can we not discover and remedy some of the causes underlying the eruption, and so effect more in the direction of preventing relapses or modifying their character? I believe we can.

Time prevents any elaborate study of the disease on the present occasion, nor is it necessary. The present writer submitted his views, with an anaylsis of one thousand cases of psoriasis, to the First International Dermatological Congress at Paris,[1] and also in a later article.[2] It may only be stated that a total disbelief in any local cause of the disease was there enunciated, and its constitutional nature vindicated. Nor do these researches lend any support to the possibility of a nervous or lymphatic origin of the eruption. Observation and study, however, have led to the conclusion that the disease is dependent upon a blood state closely allied to that belonging to gout and rheumatism.

Much more study and analysis are necessary to determine exactly in what this blood state consists, and how it is produced; but for the present it may, perhaps, be best expressed by the term "uricacidæmia," which has been of late so carefully studied and prominently brought forward by Dr. Alexander Haig, of London. It is known, of course, that this gentleman has only followed in the footsteps of many illustrious men, who have with great force urged the importance of chemical blood changes as the cause of disease. Among these stand prominent such men as Bence Jones, Murchison, Garrod, Roberts, and many others. The present writer also urged the same views as are now advocated, in regard to the etiology of psoriasis, twenty and more years ago, long before the labors of Dr. Haig had appeared.

It is unnecessary to elaborate this subject at present, except to state that it is in the urine of patients with psoriasis that we are to find the evidence of the acid blood state, and that a frequent and careful study of this secretion will often furnish us the best guide to the proper understanding of the patient and to the constitutional treatment of the disease. Careful investigation of the clinical history of the patient, including his diet and mode of life, is likewise very essential, as is also a correct knowledge in regard to his hereditary history. It is often surprising what can be discovered by patient investigation in these respects.

Finally, it may be added that, in order to care properly for a patient with psoriasis, it is by no means sufficient to regard and treat only the eruption happening to be present at any one time, but it is essential that medical observation and guidance should be extended over months and years, if we would eradicate the tendency to the eruption. It is in the light of what has preceded that I come to speak very briefly of the special point which forms the title of this paper: namely, "On the Restriction of Meat in the Treatment of Psoriasis."

It will be noticed that this is alluded to as one point only in the treatment of psoriasis; for, to be fully effective, I believe that it must be combined with every other possible element of internal and local treatment (including diet and hygiene), which experience has proved to be desirable and necessary in the management of the disease. Of these there is no time to speak now, nor is it essential to do this in the presence of the distinguished body of my colleagues here gathered.

I do, however, wish to emphasize strongly the point of my paper—namely, that free indulgence in meat is very apt to greatly aggravate the eruption of psoriasis, whereas its restriction, especially the avoidance of beef and mutton (including extracts, strong soups, etc.) will aid materially in its removal; furthermore, their continued avoidance will, I believe, contribute very greatly to the removal of the cause of the eruption, and so assist in effecting a permanent cure of the disease.

I do not wish to be misunderstood in this matter. I am not yet prepared to affirm that the eating of strong meat alone produces the eruption, or that its avoidance will surely cure the complaint. But I do believe, after carefully watching the matter for a number of years, in a considerable series of patients in private practice, that the element under consideration is of very great importance in the management of psoriasis. I have careful notes of many cases in which the improvement has been most marked as soon as this stringent diet has been rigidly observed; and also notes concerning many patients who for several years have maintained the same diet, with the most manifest gain with respect to recurrence of the eruption.

Time and space prevent a full consideration of the mode in which this plan of treatment acts in regard to the eruption; but it is explained, I think, on the ground of uricacidæmia, to which Mr. Haig has endeavored to trace so many complaints. While I am by no means prepared to agree with him in all his deductions from his carefully recorded facts, I am, from my clinical experience in many directions, very certain that in the investigations of chemical physiology and pathology we are to find the cause and cure of many diseases. I will quote a single paragraph from Dr. Haig's interesting and instructive book,[1] expressing briefly the line along which I believe investigations should be made:

"Uric acid is met with in the body and blood chiefly from two causes: 1, It has been introduced in excess by the consumption of articles of food which contain it or other members of the xanthin group, such as meat, fish, tea, coffee, cocoa, or guarana; or 2, because so much nitrogen is taken that the uric acid formed

[1] "Analysis of One Thousand Cases of Psoriasis," Trans. Cong. Internat. de Dermatologie, etc., Paris, 1889, p. 879.

[2] "Clinical Notes on Psoriasis, with Especial Reference to its Prognosis and Treatment. Analysis of Three Hundred and Sixty-six Cases in Private Practice," Trans. Med. Soc. of State of New York, 1895.

[1] Haig: "Uric Acid as a Factor in the Causation of Disease," second edition, London, 1894.

out of it (in relation to the urea, of about one to thirty-five) is not all excreted, owing to the high acidity which the salts and other ingredients of nitrogenous metabolism produce. A store is thus gradually formed in the body, to the extent possibly of from fifty to four hundred grains per year."

According to my experience, this uricacidæmia exists to a greater or less extent in psoriatic patients, and by removing or lessening it we certainly diminish the tendency to the eruption.

This is to be accomplished not only by internal medication, such as alkalies combined with tonics, and by proper hygienic measures, including bathing and exercise, but also most certainly by diet; and one of the chief features of the latter is the restriction of the nitrogenous elements in the food, especially such as are found in strong meats and their equivalents.

I regret greatly that this subject of the constitutional treatment of psoriasis cannot be fully developed at the present time, for I dislike to press a single point, when there are so very many others of great importance; but these must be left for a future occasion. I shall feel, however, that I have accomplished some good in the line of controlling this commonly intractable disease, if I can fully impress upon my hearers that they will be of service to patients with psoriasis if they will in connection with other internal, general, and local treatment, restrict wholly or largely the use of nitrogenous food, principally represented by meat.

4 East Thirty-Seventh Street.

GASTROSTOMY IN HYPNOSIS.[1]

By HENRY HULST, A.M., M.D.,

GRAND RAPIDS, MICH.

Since Egeberg suggested gastrostomy for œsophageal stenosis in 1837, the operation has not become so common as to render the reporting of new cases of it a work of supererogation.

The special interest attaching to my case lies in the fact that no anæsthetic was administered, but that the operation, which lasted over an hour, was done in hypnosis. The patient died thirty hours later.

Mr. D——, aged sixty years, noticed dysphagia last March, *i.e.*, eight months ago. At the same time rapid loss of flesh and strength set in. The smallest stomach tube was invariably arrested at about thirteen inches from the teeth; and at no subsequent trial could it be forced past the obstruction. Definitely localized pain at the seat of the trouble was not marked, nor was there more than a vague and transient sensation of uneasiness anywhere except in the right supraclavicular space. There were no enlarged glands, so that the pain there was probably of the nature of a referred sensation. Vomiting soon became a prominent symptom. No blood came, and the vomit consisted of what he had eaten and much mucus. The breath was often foul and the tongue heavily coated, but the vomit was not of offensive odor. The difficulty in swallowing increased, but with surprising intermissions, lasting sometimes for days. Thus, sometimes for days every effort at swallowing produced vomiting and more or less pain in the right supraclavicular space, but suddenly he would experience relief. Liquid and even solid food would slip down quite easily, and he would declare that he was certainly getting well now. Frequently this change was so abrupt and so marked as to startle me into doubting somewhat the organic nature of the trouble. But the tube would not go down, and emaciation progressed in spite of vigorous rectal feeding until he had dwindled down to about one hundred pounds from one hundred and eighty, his former weight. So that, in view of the fact that "in persons over fifty years of age, persistent difficulty in swallowing, accompanied by rapid emaciation, usually indicates œsophageal cancer" (Osler) the outlook was bad. During the last two months practically no food, solid or liquid, reached his stomach. He was very hungry most of the time; rectal feeding could not keep him up, and he felt life slipping away from him. Yet, rather than suffer pain in the right supraclavicular region from attempting to swallow, and sooner than retch and vomit, he chose to starve slowly, until finally, when he had become thoroughly exhausted, he consented to the operation.

He entered Butterworth Hospital, October 26, 1896. Strychnine, one-fortieth of a grain, was given hypodermically every four hours, and rectal feeding was continued to the limit of toleration. On account of his prostration it was feared that he might die under the anæsthetic, and as I had occasionally hypnotized him since 1893, and had found him to be a fairly good, though in no way a remarkable subject, I resolved to try hypnotic suggestion instead of chloroform. The evening before the operation, to prepare him by a good night's rest and to remove from his mind all fear of the operation or its outcome, I proposed to put him to sleep for the night. He consented gladly. After he had been got ready I told him to go to sleep, and promptly he shut his eyes and his breathing became slow and deep. I raised his arm and it remained that way, cataleptic. I put it down and spoke to him somewhat as follows: "Mr. D——, sleep soundly to-night; do not wake up till morning, and then you will be rested and fresh. You positively long for the operation, for you must be helped, and you will suffer no pain because I shall put you to sleep soundly." The next morning he was cheerful and quite ready. The nurse said that he had slept quite well and that she had given him the hypodermic injections without awakening him. He quietly bid good-by to his wife and children and was put to sleep on his bed, the same as the night before, so that he might be brought into the operating-room and treated like one under chloroform. Strict asepsis was observed. When everything was ready, I made sure that he was *en rapport* with me and talked to him quietly a while, stroking the site of the proposed operation and assuring him that he would be very comfortable while we worked on him, and directed him to lie perfectly still.

Dr. Perry Schurtz, of this city, assisted me to do the Ssabanejew-Frank gastrostomy, October 28th.

The first cut was made about three and a half inches long and one-third inch below and parallel with the left costal arch. The colon presented and the liver made its appearance in the opening with each inspiration. The stomach was found contracted and supporting bunches of angleworm-like veins. Its fundus could not be drawn from under the ribs without undue force, so that a part of the distal half of the organ was pulled out about two inches and stitched to the parietal peritoneum with a dozen interrupted iron-dyed silk sutures. Silkworm-gut sutures, one at each end of the incision, were placed so as to anchor the stomach and afterward buried. The second opening was made one and a half inches above the first, parallel with it and one and a half inches long. The resulting bridge was undercut, the stomach drawn through the second incision, the first one closed with interrupted silkworm-gut sutures; the stomach, now protruding out of the second incision was opened with scissors and attached to the skin with interrupted silk sutures, and the dressings were put on.

A little later the dressings were made tighter, as it was found that there was some oozing. He was kept in hypnosis about four hours longer. When I awak-

[1] Read before the Academy of Medicine of Grand Rapids, Mich., November 9, 1896.

ened him by touching his chin and asked him, "How are you now, Mr. D——," he answered, "I feel fine." His pulse, however, which was as good during the operation as before, gradually went up to 132 and became very feeble. Hypodermic injections of a pint of normal salt solution, repeated in the evening, reduced the pulse to 118. Next morning it was 116. Another pint of salt solution was given under the skin and the patient fed for the first time through the new opening. The wounds looked well. About noon he grew uneasy, breathing became rapid, he complained of dyspnœa (embolism?), and died thirty hours after the operation.

Post-mortem, two hours later, showed that peritoneal union had already occurred. The œsophageal stricture cut out admitted the points of a closed Péan forceps; the surrounding tissues were hard, and an ulcer had made its way almost through the walls of the œsophagus on its posterior surface.

In an article entitled "Therapeutic Uses of Hypnotism," MEDICAL RECORD, March 4, 1893, I said: "Although hypnotism will never usurp the place of chloroform and ether, it is possible to render many minor and even capital operations painless by means of it, the patient watching every step of the operation, and assisting, if desired." My experience with it in surgery was then limited to three minor cases. Gastrostomy was, however, the most serious operation I have dared to undertake in hypnosis; for I quite agree with Moll that "analgesia cannot sometimes be induced at all, and sometimes only after repeated trials. The excitement before the operation increases the difficulty."

On the other hand, the case I have reported proves that Hirsch overestimates the difficulties when he says that "Grössere Operationen wird man wohl kaum in der Hypnose vorzunehmen sich entschliessen können."[1]

PYTHIAN TEMPLE, December 6, 1896.

THE METHOD OF INFILTRATION ANÆSTHESIA: ITS TECHNIQUE AND SUPERIOR ADVANTAGES FULLY SET FORTH.

BY WILLIAM J. ROBINSON, PH.G., M.D.,

NEW YORK.

IT is a surprise and a pity that a method so remarkable in its effect and so easy of application, a method with which every physician and surgeon in Europe is now perfectly conversant, a method that has proved an inestimable boon to surgeon and patient alike, should be so little known and so little used in this country. The method of local anæsthesia by infiltration, introduced and perfected by Dr. C. L. Schleich, of Berlin, is unquestionably one of the most important and beneficent discoveries of the last decade of our century, and I am certain that those who are using this method in their daily practice will not consider this assertion too enthusiastic or overdrawn.

Scepticism is a good thing, and is more desirable in medicine—a science which, in spite of the tremendous advances made, still borders quite closely on empiricism—than in any other science. It would certainly be a blessing if the members of the medical profession possessed a good deal more of it than they do, particularly with regard to the new synthetics and the innumerable nostrums so highly lauded by the glib-tongued representatives of the manufacturing firms. But scepticism, like every other good thing, may be misplaced and misapplied. I confess that I was also somewhat sceptical as to the efficacy and general applicability of the method, but after I had seen Dr. Schleich use it in over a hundred operations—minor and major—and after having employed it myself in nearly one hundred cases, my scepticism became transformed into boundless confidence and enthusiasm. As many abstain from employing this method because they are under the impression that it requires a special technique, and are surprised at its simplicity after having seen it once in practical operation, and as I failed to find in our medical journals a thorough, explicit, and satisfactory exposition of it, it shall be the purpose of this article to present the method in such a form as to make its practical application easy for the merest tyro in medicine. I shall plead guilty to the charge of being too elementary rather than to that of being obscure.

First let us become familiar with the solutions employed for the injection. The formula of the solution commonly and I may say almost exclusively used is as follows:

NORMAL OR MEDIUM SOLUTION, OR SOLUTION NO. 2.

Cocaine hydrochlorate.....	1.0
Morphine hydrochlorate.....	0.25
Sodium chloride c. p.....	2.0
Sterilized distilled water.....	1,000 c.c. or 1 litre.

To prevent speedy decomposition, twenty drops of a five-per-cent. solution of phenol are added to each litre of the solution. But even with that addition the solution decomposes quite rapidly, and it is therefore advisable to make it fresh as often as possible and in small quantities (it is superfluous to add that the least sediment in the solution unfits it for use). I usually order the following quantity (preserving, of course, the right proportions, as is seen in the formula):

Cocaine hydrochlorate.....	gr. ij.
Morphine hydrochlorate.....	gr. ss.
Sodium chloride.....	gr. iv.
Sterilized distilled water...	♏ 2,000 (or ʒ iv. + ♏ lxxx).
Sol. carbolic acid, five per cent.....	gtt. ij.–iij.

Of this, the normal or medium solution, from three to four ounces (90 to 120 c.c.) may be injected at one sitting. There are two other solutions: the "strong" solution or solution No. 1, and the "weak" solution or solution No. 3. Their respective formulæ are as follows:

STRONG SOLUTION, OR SOLUTION NO. 1.

Cocaine hydrochlorate.....	2.0
Morphine hydrochlorate.....	0.25
Sodium chloride.....	2.0
Sterilized distilled water.....	1,000 c.c.

WEAK SOLUTION, OR SOLUTION NO. 3.

Cocaine hydrochlorate.....	0.1
Morphine hydrochlorate.....	0.25
Sodium chloride.....	2.0
Sterilized distilled water.....	1,000 c.c.

It is well to call attention to the fact that the difference in the three solutions is only in the quantity of cocaine, the "strong" solution containing twice as much cocaine as the normal, and the "weak" solution ten times less than the normal; the amount of morphine and sodium chloride being the same in all three solutions. But I want again to emphasize the point that we can get along very well with the normal solution alone. The strong and the weak solutions are to be used only exceptionally—the former, for instance, in severe acute inflammation; the latter when it is necessary to infiltrate very large areas of tissue, and when one or two pints of solution may be required. Of the strong solution one to two ounces (30 to 60 c.c.) may be used during one operation, and of the weak one eight to sixteen ounces (250 to 500 c.c.). Personally, when I have occasion to use the weak solution, I use a modified formula, in which the amount

[1] Dr. Max Hirsch: "Suggestion und Hypnotismus," p. 49.

of morphine is diminished one-half and the amount of cocaine doubled. It is:

Cocaine hydrochlorate	0.2
Morphine hydrochlorate	0.12
Sodium chloride	2.0
Sterilized distilled water	1,000 c.c.

This solution contains only one grain of morphine to the pint, and seems to me preferable in cases in which it is to be employed in very large quantities.

Right here I want to answer two criticisms made sometimes by our friends, the medical sceptics, who desire to belittle Dr. Schleich's discovery. One assertion is that the proportion of the drugs is so small that they cannot possibly exert any effect, and that plain sterilized water would act in exactly the same manner. To this assertion I need only reply: "Try it, gentlemen, and see for yourselves." Dr. Schleich experimented on his person hundreds of times, and the marks of the numerous jabs of his large syringe can still be seen on his arms and on other parts of his body. He then tried the solutions in several thousand cases, and he found that the proportions were exactly right—neither more nor less would prove satisfactory. Infiltration with plain water certainly produces anæsthesia, but is accompanied with discomfort and is of a momentary character. The second assertion is that the solution does not anæsthetize at all, but acts by "suggestion." Well, this criticism is really unworthy of consideration. Just hear a patient, with his or her eyes away from the field of operation, scream, when you go with the knife one-sixteenth of an inch beyond the infiltrated area! As I heard Dr. Schleich say: "It must be 'suggestion' developed to a pretty fine point, that can, without the aid of sight, discern a difference of one millimetre."

Now, as to the method of using the solutions. Though an ordinary hypodermic syringe may be employed, in order to save time, labor, and unnecessary puncturing, a large and strongly made syringe is advisable. The syringe should hold 5 to 15 c.c. (1¼ to 4 drachms), and should be provided with strong, large needles, some of them curved. After having prepared the skin antiseptically and filled the (previously asepticized) syringe, we proceed with the injection. But before we do so, we must—if we want the operation to be absolutely painless—anæsthetize the first point of insertion. For this purpose we may use a spray of ether or ethyl chloride, but the simplest and least troublesome way is to touch the skin with pure liquefied carbolic acid (with a stick of wood, or a bit of cotton on a cotton carrier dipped into it). For mucous membranes the best thing to use is a crystal of cocaine hydrochlorate. Having anæsthetized the point of insertion, we begin to inject. But remember—and this is a very important point, frequently, as I have observed, disregarded by the beginner—you are not making a *hypodermic*, but a *dermic* injection; you are not injecting under the skin into the cellular tissue, but into the skin itself (or into the deep tissues, as the case requires). You therefore do not hold the needle perpendicularly or obliquely to, but almost parallel with, the skin. After pressing the piston evenly and gradually, you will notice a round, white —dead-white—spot, absolutely anæsthetic—the so-called wheal (not bubble, because it is not a bubble at all). The original direction of Dr. Schleich was to withdraw the syringe after the wheal reached the size of about a penny, reinsert it within the radius of the first wheal, inject until a new wheal is formed, withdraw, reinsert again, and so forth, until the entire area where we intend to operate has been infiltrated. I consider this oft-repeated withdrawing and reinserting of the needle unnecesary. With a strong syringe and needle we are able with one insertion to form a wheal two or three inches in length, and in any desired direction. I have done many minor operations without having had to insert the needle more than once. Though perhaps not very important, it is nevertheless advisable not to puncture the skin unnecessarily, if it can be avoided.

After the area to be operated upon is completely and thoroughly infiltrated, you may proceed with your knife or red-hot iron, and the patient will look on with perfect equanimity, as if somebody else were operated on, and he will experience no more pain until the operation is over than he would if he were in the deepest chloroform or ether narcosis; and he will certainly behave more orderly.

As to the *rationale* of the method, it is sufficient to state that the anæsthesia depends, first, upon the direct action of the cocaine and morphine on the nerve endings; second, upon the absolute ischæmia produced by the injected fluid; and third, upon the high pressure to which the tissues are subjected.

Now we come to the question: Wherein is Dr. Schleich's method superior to local anæsthesia by cocaine and to general narcosis by chloroform and ether?

Its points of superiority over cocaine are: 1. It is free from the possible toxic or fatal effects of cocaine, there being no record of any ill effects in tens of thousands of operations. 2. With the Schleich method areas of such size and depth can be operated upon and operations of such magnitude performed as would not be dreamed of with cocaine anæsthesia. 3. The effect is more lasting—ordinary cocaine anæsthesia lasting from two to five minutes, infiltration anæsthesia from fifteen to twenty minutes.

Its superiority over chloroform and ether may be considered in three different groups of cases. First, there is, as we know, a large class of patients in whom general anæsthesia is absolutely contraindicated, such as those with advanced pulmonary or renal disease, fatty degeneration of the heart, diabetes, etc. All those sufferers, until the advent of the Schleich method, were obliged to forego the benefit of an operation, as the administration of an anæsthetic was accompanied with too great a risk. Now, if such subjects are suitable for the infiltration method—and Dr. Schleich performs by its aid capital operations, such as amputations, laparotomies, nephrectomies, etc.[1]—they can be operated upon with as much safety as the healthiest person. Second, there is a number of persons who will not submit to an operation, because they are afraid of chloroform or ether, though there be no contraindication as far as their heart, lungs, and kidneys are concerned. For instance, almost the first patient I operated upon, on my return from Europe, was a young woman with two lipomatous tumors. They caused her pain and annoyance, but she had such mortal fear of an anæsthetic that she would never agree to an operation. When I assured her that I would remove the tumors without giving her an anæsthetic and without her feeling any pain, she readily consented, and her joy after an absolutely painless operation of a few minutes' duration was unbounded. And third, in those cases in which general anæsthesia is not contraindicated and is not objected to, the infiltration method has the following advantages: 1, We can operate in less time; 2, we need fewer assistants, we need no anæsthetizer, no nurses to hold the patient down: and 3, last but not least, we avoid the deadly treachery of

[1] The impression that Dr. Schleich performs *all* major operations exclusively by the aid of his method is wrong. In certain operations, during certain stages—as, for instance, in amputation of the extremities, while sawing the bone—he administers a general anæsthetic of his own composition. This anæsthetic is claimed by him to be perfectly harmless, and consists of ether, alcohol, and rhigolene (petroleum ether). It has a very low boiling-point.

the general anæsthetics, which, no matter what precautions we take, always lurks in them and occasionally carries off a patient on the operating-table, before we have a chance to do any operating. I can do no better to illustrate the difference between the two methods and the superiority of one over the other, than by narrating the circumstances of an identical minor operation, which by a coincidence I saw performed twice on the same day, under general anæsthesia and under the Schleich method. The trifling operation consisted in removing the terminal phalanx of the thumb.

Under general chloroform anæsthesia it was performed in one of the large Berlin hospitals. The patient was a powerful man and was very hard to anæsthetize; his struggling and screams could be heard all over the hospital. It required three persons to restrain him. And without any premonition his pulse became imperceptible and his face cyanosed; the administration of the anæsthetic had to be discontinued; heart massage and artificial respiration were resorted to, and the patient came to in a short time. The operation was finished without anæsthetic. This patient certainly came within an ace of throwing off his mortal coil.

The second time on that day I witnessed it in Dr. Schleich's polyclinic. The doctor infiltrated, amputated the joint, and stitched the flaps in a few minutes, without any assistance, the man all the time sitting on a lounge, blissfully smiling and enjoying the performance. Then he walked out to resume his daily work. Comment is unnecessary.

And let me recall here an incident that occurred in this city some time ago. A man got a splinter in his finger, it became gangrenous, and an operation was decided upon. During the administration of the anæsthetic the man died. The physicians were sued for $5,000 damages for malpractice, and had to undergo the annoyance, anxieties, and heavy expenses of a long trial. Had the Schleich method been known and practised at that time, the doctor would have removed the gangrenous finger at his office, the man would probably be still among the living, and two reputable physicians would have escaped much vexation and embarrassment.[1] It is therefore my opinion that a physician who in cases suitable for infiltration anæsthesia chooses chloroform or ether commits an unwise and a morally reprehensible act.

112 East One Hundred and Twenty-Eighth Street.

Blood as a Therapeutic Agent.—After a trial of various organic extracts in the treatment of osteo-arthritis, Macalister (*Lancet*, November 28, 1896, p. 1,512) reflected that the blood must of necessity contain the secretions of the various ductless glands and that its administration might prove of therapeutic use. He therefore had prepared a blood residue by evaporating ox blood in vacuo at a temperature not exceeding 100° F. It was found that each quart of blood from the jugular vein yielded from nine to eleven ounces of dry residue. Compressed into tabloids, this was used in the treatment of several cases of osteo-arthritis, in some of which at least most marked improvement resulted. Believing that other elements than the red cells are influenced by the oxygen in the lungs, Macalister was next led to use carotid blood, which, it was found, yielded less residue by two ounces to the quart than venous blood. The venous residue is a fine light-brown, cacao-like powder, while the arterial residue is much darker in color and finely granular in consistence. Bone marrow also has proved useful in the treatment of osteo-arthritis, one patient treated exclusively with it recovering movement in all of the joints.

SOME POINTS IN THE TECHNIQUE OF THE SERUM TEST FOR TYPHOID FEVER.

By CHARLES F. STOKES, M.D., U.S.N.

Early in the study of inoculated hanging-drop cultures of the typhoid bacillus, the writer was impressed with the difficulties encountered in the manipulation of cover glasses, when hollow or concave slides were used. The covers frequently have to be removed for the addition of serum, culture, or water, or for sterilization and cleaning, when they are found to be closely adherent to the slides and may be easily broken.

For some time the writer has used rubber and metallic cells in the study of hanging-drop cultures. The rubber rings may be had at the optician's, while the metallic rings, which are the better for this purpose, may be readily made by evenly flattening the small metallic rings used in hanging window curtains and by cementing them to the slides with marine glue. They may be superimposed if of insufficient elevation. The diameter of the cells should be a trifle less than that of the covers used, so that the overhanging margins of the latter may be easily engaged in the forceps. The cells should be from one-sixteenth to one-eighth of an inch in depth.

Staining the bacteria in clumps is of importance and interest. As soon as the characteristic clumping of the bacilli in an inoculated hanging drop has been satisfactorily demonstrated, the writer removes the cover glass, dries the specimen, and carefully stains the bacteria with Ziehl's solution. The specimen is again dried and mounted in Canada balsam. The mount is labelled with the name and age of the patient, day of the disease, and a note made as to the activity of clumping. The control inoculation may be stained and mounted on the same slide, and the clumping then beautifully demonstrated by contrast. The slides, after careful labelling, are put away for future reference.

To physicians living out of town, and those without laboratory facilities at hand, such double mounts are most instructive and convincing. Then, too, such mounts, made at intervals in the course of the disease in a particular case, are of great value in studying the activity of clumping, as well as the size and shape of the clumps in the different stages of the attack. It must be remembered that the relative amounts of culture and serum have a direct bearing on the rapidity of clumping.

United States Naval Laboratory and Department of Instruction, Brooklyn, N. Y.

X-RAY METHOD OF EXAMINING THE HEART.

By C. F. DISEN, M.D.,

Minneapolis, Minn.

While viewing the pectoral region through the fluoroscope and observing the shadow of the heart, a method of nearly accurate estimation of its size, normal or abnormal, occurred to me. Putting the method instantly in practice, I marked out what should be the normal contour of the heart on the anterior surface of the chest wall. Then I bent a copper wire in the shape of the tracing and affixed it on this with adhesive plaster. Having the patient facing the Crookes tube, I looked through the fluoroscope from behind between the spine and the scapula, when I plainly saw the wire outlining the shadow of the heart. It may be wondered how the heart can be seen when the soft parts are said to be penetrable by the rays, but the different degrees of penetrability, according to the density of

the tissues, enables one to do so. Yet it may be necessary to proceed in a certain way, as at a high power the *x*-rays seem to dissolve everything, even bone and iron. Using as a generator either a powerful static machine or an induction coil of at least 8" spark, you let your machine work so as to produce the strongest *x*-rays at your command, when you may see only the scapula, the ribs, the left part of the spine, or the sternum, not to forget—plainest of all—your wire in front. Having familiarized yourself with your landscape, you now very gradually reduce the brightness of the *x*-rays—in the case of a static machine by reducing the speed—and you will observe the shadow of the heart, extending within or outside your wire. Sometimes you can see a thinner and larger shadow superimposed on a smaller and thicker one, the former representing the heart in diastole and the latter the same in systole. As generally the left line of the heart is all we look for, it may be sufficient for the busy practitioner to affix an almost straight wire, extending from the third to the sixth rib at a proper distance from the left sternal border. Naturally, you may fail to see the heart unless you locate your fluoroscope opposite the organ, which I roughly estimate by marking off a spot to the left of the spine opposite the fourth intercostal space in front. On this mark I centre the fluoroscope. Obvious optical reasons make it preferable to look from behind rather than from the anterior aspect. I think the readers easily will understand my method and find it vastly superior to percussion in giving positive information. Other organs, as the spleen and the kidneys, are probably explorable in the same manner, and instead of using the fluoroscope pictures may be taken, but the necessarily longer exposure to the *x*-rays may produce a burn.

AN EXTRAORDINARY CASE OF CROUP, COMPLICATED WITH PNEUMONIA, INTUBATED BY DR. O'DWYER AND TREATED WITHOUT FOOD, ANTIPYRETICS, OR ALCOHOL.

By A. MONAE LESSER, M.D.,

NEW YORK.

On the evening of November 5th I called Dr. O'Dwyer in consultation to a case of croup with a developing pneumonia. The patient, Howard S——, male, aged two years, had been apparently perfectly well up to five o'clock in the morning, November 5th, when suddenly he began with a croupy cough; still it was apparently not different from like attacks of cough which he had on previous occasions.

His cough, however, grew worse. I was summoned. I saw him at 9 A.M. His temperature then was 103° F.; pulse, 120; respiration, 25. The family being able to afford every luxury, and not so much for the apparent necessity, competent nurses were secured to attend and closely watched the symptoms. Temperature, pulse, and respiration increased in severity with every hour until three o'clock in the afternoon, when, although the temperature diminished, the pulse increased to 150 and respirations to 56. In the evening, when Dr. O'Dwyer made his first call, the temperature was 102.4° F.; pulse, 140; respirations, 56; and, although breathing was somewhat labored, no evidence of a membrane could be found in the pharynx, so far as we could see.

From the fact that the temperature and croupy cough had somewhat diminished and the rhythm of respiration continued to increase in proportion with the pulse, we believed that the larynx was of less importance and that the bronchioli were involved, progressing to lobular pneumonia.

We remained about an hour, during which time the respirations increased to 60, while the symptoms in the larynx did not seem to increase in severity. At twelve o'clock, however, the temperature began to rise, and the record showed 102.4° F.; pulse, 130; respiration, 62. In the morning, at four o'clock, we were hurriedly summoned again; the breathing had become labored, and on my arrival I found the patient cyanotic. I gave one-four-hundredth of a grain of nitroglycerin hypodermatically, which relieved the paroxysm; but before Dr. O'Dwyer's arrival (an hour having elapsed) the child had two more paroxysms, making three in all in one hour, relieved in the above manner. We found that immediate relief of the larynx was urgent. We swabbed the throat for a culture test, although still no membrane could be seen. The insertion of the tube relieved the little patient's asphyxiated condition. It was then 7 A.M. The course of the case, the sound so peculiar to membrane in the trachea, and the early complicating pneumonia prompted us to exclude everything but diphtheria. We decided to inoculate the patient with antitoxin, and injected two thousand units (under perfect antiseptic precautions). His respirations were then 62, and his pulse 130. No alcohol, antipyretic, or food had been given for twenty-four hours. The child fell asleep for one-half hour.

At 10 A.M. the temperature was 101.6° F.; pulse, 140; and respiration, 66. From that hour, however, pulse, temperature, and respiration rose again. On the evening of November 6th the temperature had risen to 103.4° F.; pulse, 180; respirations between 80 and 90 (taken while the patient was asleep). At our evening visit, Dr. O'Dwyer doubted the probability of the child being alive the next morning; but, should this be the case, he advised giving another dose of antitoxin.

Until the next morning, November 7th, the condition of the patient seemed rather hopeless, his pulse at times not being countable, although his heart sounds were comparatively clear. Paroxysms of asphyxia occurred from time to time, but became less severe and less frequent as the night passed on, and at 7 A.M., with the temperature of 102.6° F., the pulse fell to 180 while he was asleep and respirations to 88. We gave a second dose of antitoxin, the same as before. In the evening, temperature rose to 104° F.; respirations and pulse when he was asleep assumed a rhythm of two pulsations to one respiration, although the pulse was 172 and it was of fair strength. As yet no food, antipyretic, or alcohol had been given, and naturally Dr. O'Dwyer felt somewhat nervous; but my assurance, and the fact of having treated a similar but much milder case with him on a previous occasion, with good results, and, most of all, it being my case, he did not interfere with my treatment, which was plenty of water, small doses of nitroglycerin from time to time, and hypodermatic injection of one-half a milligram (one-one-hundred-and-twentieth of a grain) of strychnine nitrate, one-tenth of a drop of tincture of lobelia every two hours, half a drop of tincture of baptisia also every two hours, and a few grains of plain salt at intervals. Both apices of the lung could be plainly heard to be infiltrated, and there was no doubt regarding the case.

On November 8th and 9th the temperature, pulse, and respiration were about the same, although slightly diminished in the evening. Owing to wrong information of the child's age, Dr. O'Dwyer inserted first a three-to-four-year tube. This seemed to annoy the child, but his condition at the time was such as to make it not safe to change it; but on the morning of November 8th, the fourth day of the disease and third day after intubation, he removed the tube. Soon, however, the difficulty of breathing increased again, show-

ing plainly that the disease was still in the larynx and the necessity of reintubating, which was done with a two-to-three-year tube. The child was strong enough to bear the intubation and the preparations belonging to it, although Dr. O'Dwyer confessed fear that, owing to the want of nourishment, it might collapse.

On the evening of November 9th, the fifth day of the disease, the temperature, although it had been at 101.8° F. all day, again rose to 103.6° F.

On November 10th the highest rise was to 102.4° F., at three o'clock in the morning. The pulse had fallen to between 120 and 130, and respirations to 50; and at eight o'clock on the same morning the pulse had fallen to 120; respirations, 50.

The patient, upon awakening from a sleep, asked for some food, and received a tablespoonful of junket and three plain crackers. The temperature slightly rose again, but not above 101.8° F. The patient gradually improved, and on November 12th, the seventh day of the disease, the temperature was normal; pulse, 98; and respiration, 26.

From November 5th to November 10th (five full days) the patient had not partaken of any food save water, and from that day the quantity for each meal was gradually increased as he grew better. Food was given only when the child begged for it and was not forced upon him. It was also strictly observed that when a meal, no matter how small in quantity, was given him, no food was allowed again until the full time had elapsed which physiologists describe to be required for the digestion of such food. As for the alcoholic stimulants, it was evidenced that the child got along very nicely, although it was a case in which ordinarily it would have been given. The temperature (always taken in the rectum) was looked upon with indifference, its highest point having been 104° F., and no direct antipyretics were administered.

Dr. O'Dwyer agrees with me that there are a number of remarkable points about this case: 1. The extraordinary rapidity of the course from a mild-appearing croup to one of the most severe type, without a positive proof of diphtheria bacilli. 2. The rapidity with which the pneumonia made its progress, and despite the severe symptoms which attended the case, aside from the paroxysms, the patient felt comparatively easy. 3. The fact that, despite every symptom of a most severe type of genuine diphtheria except the membrane, we could not get a satisfactory culture after three trials. The first two specimens answered negatively, and the last, which was taken directly from the tube, did not prove satisfactory.

Regarding my treatment, without food, alcohol, or antipyretics, Dr. O'Dwyer said: "While I still may be too timid to try it in every instance, I must state that in this case it has acted most satisfactorily. The case was of so severe a character that recovery could hardly be looked for. One thing is sure, that the stomach and intestines never interfered with the action of the diaphragm, which in such cases is a matter of vital importance. If the case was not one of diphtheria, it is a most remarkable one; if it was, of course the facts are the same, but the antitoxin takes away considerable of the danger of the case."

Qualities of the Old-Time Surgeon.—John of Arden, the sergeant surgeon of Edward III., in 1346, gives a "Description of ye qualities which ought to be in ye surgeon that performeth any operation of chirurgery: First, that he be devout. Secondlie, charitable to ye poor. Thirdly, to use few words. Fourthly, to avoid drunkenness. Fifthly, to be chaste, both in words and gestures, as well as to fear not. Sixthly, not to undertake an incurable disease."—*Medical News.*

SKIN GRAFTING OF AN INFANT TEN DAYS OLD.

By D. F. SULLIVAN, M.D.,

HARTFORD, CONN.

I was recently called to attend an infant that was badly burned. Imagine my astonishment at finding my patient less than a half-hour old, and its right side from above the nipple to within an inch of the groin, over an area about two and a half inches wide, burned to the muscle by a hot flatiron that was wrapped in a towel and placed near the baby to warm it, while the "neighborly accoucheur" was "pulling away" the afterbirth. For three days the infant's condition was precarious, but on the tenth day the denuded surface was in fit condition for grafting, which was done with splendid facilities. Eight members of the family, the oldest twelve years, were willing contributors and afforded ample material. Twenty-two grafts, each about eight millimetres long and three wide, were taken; twelve were taken from the three oldest. To be brief, the dressing was removed on the fourth day, and but six of the twenty-two grafts showed signs of granulating, and these were taken from the two youngest, three years and two years respectively. I decided to graft the next time from suckling infants, if possible. The thickly settled district facilitated the carrying out of this idea, which was promptly executed by the aid of eleven sympathizing nursing mothers. In all eleven pieces of skin were taken from the thighs of the tiny contributors, a 0.6 per cent. salt solution being used as before and every antiseptic precaution being taken. On the fourth day following I removed the dressing and every graft looked healthy; those taken from the nursing infants were healthier apparently than the rest. In twenty days the entire surface was covered, and the babe was none the worse from an experience most uncommon. I fail to find on record any case of an infant burned in such a novel manner, at such an age, surviving the shock, and living to be skin grafted successfully from material furnished mostly by suckling infants.

TWO SPECIMENS OF URINE IN WHICH AFTER NEARLY TWENTY YEARS HYALINE AND GRANULAR CASTS AND EPITHELIAL CELLS WERE PERFECTLY PRESERVED BY MEANS OF CHLORAL.

By W. W. KEEN, M.D.,

PROFESSOR OF THE PRINCIPLES OF SURGERY AND OF CLINICAL SURGERY, JEFFERSON MEDICAL COLLEGE, PHILADELPHIA.

In the *Philadelphia Medical Times*, 1873-74, vol. iv., and in the *American Journal of the Medical Sciences* for July, 1875, I published two papers on the value of chloral as a preservative of anatomical material. Recently, in going over some specimens in my museum, I came across three which are of interest.

1st. Three bottles of urine, to one of which I had added ten grains of chloral to the ounce on June 1, 1877, to the other on June 27, 1878, and to the third on June 30, 1878. These, therefore, had been kept for about a little over and a little under nineteen years. I gave them to Dr. D. Braden Kyle for examination of the sediment, who reported as follows:

In the first, after nineteen years and a half, hyaline casts and granular epithelial cells were found perfectly preserved. In the second, after eighteen years and a half, there were granular casts and triple phosphates. In the third the examination was negative.

A result such as this, after so many years, is surprising, and I have no doubt that this method of preserving the sediment for microscopical examinations will be of value.

The urine had been in ordinary cork-stoppered bot-

tles, and presents after so long a time no odor or other evidence of decomposition.

I pointed out, however, in my earlier papers, the fact that chloral interferes with the test for sugar, as it reduces copper.

I came across also two specimens, one of a fœtus six weeks old, which had been in the chloral solution, forty grains to the ounce, since March 10, 1874, approaching, therefore, twenty-three years. To the eye the fœtus was perfectly well preserved. The eyes, the small sprouting arms and legs, even the slight beginning differentiation of the five fingers could be made out. I asked Dr. Kyle to see by making a section of them whether the tissues were well preserved, but the moment that his forceps touched the fœtus it was so brittle that it crumbled to pieces. The same fate befell also some muscle which I had removed from a subject injected with zinc January 12, 1875, and had put in chloral, ten grains to the ounce, on May 4, 1875, over twenty-one years. This also was too brittle for any sections to be made.

It may be that possibly in the case of the fœtus the solution was too strong, and in the case of the muscle that the addition of zinc as well as chloral may have made some difference.

I thought it might be of interest to your readers to report the effect of chloral after so long a time, and especially to point out its value as a preservative of organic sediment in urine.

EUCAINE IN MINOR SURGERY.

By THOMAS JEFFERSON YARROW, Jr., M.D.,

RESIDENT PHYSICIAN, EPISCOPAL HOSPITAL, PHILADELPHIA.

The following is a brief report of the use of eucaine hydrochlorate in a series of thirty-five minor surgical operations, performed in the surgical dispensary of the Episcopal Hospital, Philadelphia, service of Dr. Adinell Hewson.

Method of using: A heat-sterilized aqueous solution of the drug was used, ranging in strengths from one and one-half to ten per cent. The field of operation having been thoroughly prepared, an aseptic elastic ligature was applied, and ten to thirty minims were slowly injected by a hypodermic syringe into and about the point of operation. The ligature was retained until the operation was completed.

One of the advantages that eucaine possesses over cocaine is that, while the latter drug is decomposed during heat sterilization, the eucaine is not, and retains its full anæsthetic power.

The aseptic ligature was applied, when possible, above the seat of operation, and in only two cases was any physiological action of the drug observed. These two cases had marked slowing of the pulse for about five minutes, the pulse being slow, full, and strong, about 56 to 63 per minute.

Eucaine did not seem to produce ischæmia of the part, such as is observed during the use of cocaine. After the removal of ligature, free bleeding occurred in nearly all the cases immediately. In this it differs from cocaine, which by its vasomotor constriction often delays hemorrhage.

In conclusion: Eucaine may be used successfully in all of the minor surgical operations in which cocaine has been formerly employed. Eucaine appears to have advantages in that it can be rendered sterile in solution by boiling. Its physiological effects are slight, if any, when used in moderate quantities. There appears to be no throbbing pain after operation. In the average case, twenty minims of a four-per-cent. solution are required to produce complete and satisfactory local anæsthesia.

A CASE OF FOREIGN BODY IN THE EAR.

By FREDERICK N. C. JERAULD, M.D.,

NEW YORK.

Although clinical statistics show that foreign bodies in the external auditory canal are not so frequent as might at first be supposed, they are common enough to be frequently met with in general practice. In fact, the general practitioner is called upon to extract the foreign body as frequently if not more so than is the specialist.

The ones that usually fall into the hands of the specialist are those cases in which the foreign body has been in the ear for some little time, and has not given rise to any very active symptoms in the beginning. Let a man get a bug in his ear, he will not stop to look for a clinic or a specialist, but will go at once to his family physician.

In twenty-seven hundred and eighty-four cases treated in the New York Eye and Ear Infirmary, a foreign body was found in only thirty cases; and Dr. Albert H. Buck, clinical professor of diseases of the ear in the College of Physicians and Surgeons, New York City, says his records show only about one-half of one per cent.

These are, however, the records of the specialist. Could we get a record of all ear cases treated in New York City, both by specialists and general practitioners, the percentage of foreign bodies would undoubtedly be much greater.

All forms of foreign bodies found in the ear might be divided into three classes, according to the character of the foreign body.

The first class consists of sticks, pebbles, peas, beans, beads, lead from pencils—in fact, anything with which a child might play. This class is the one most frequently met with, and the patient is usually a child. The foreign body may have gotten into the child's ear while the latter was at play, or, as frequently happens, been put in by the child or his playmates.

The second class consists of wads of cotton, which are put into the ear by the patient as a protection. This class is usually found in old people. They put one wad in the ear; then, forgetting that it is there, put another on top of the first. The first wad is thereby pushed into the auditory canal, forgotten, and may remain for a longer or shorter time, until finally the patient begins to grow deaf.

The third class consists of various forms of insects, such as the fly, bedbug, waterbug, etc. They may be found with equal frequency in children and adults, and usually gain access to the ear while the patient is sleeping.

A patient with a bug in the ear would naturally be aware of its presence, and would go at once to a physician; whereas an old man with a wad of cotton in his ear would not be aware of its presence, and would not consult a physician until he began to notice that he was growing deaf.

A child is apt to go for months with a foreign body in the ear, provided it is out of sight and gives rise to no pain. As the ear wax collects on the foreign body, the canal becomes filled, and then it is that the mother notices that the child is growing deaf and consults a physician.

It is exceedingly rare for an adult to get a foreign body of the first variety in the ear and not be aware of its presence. Such cases do, however, occur, and I refer below to one of that kind which came to my notice a short time ago.

Mr. L——, aged twenty-six, until this fall had never had any trouble with his ears, and his hearing had always been perfect. He noticed in September that he was growing rather hard of hearing in his left ear. The deafness increased to such an extent that he

decided to consult a physician, and came to me on October 24th. He had suffered absolutely no pain or discomfort other than the deafness. The latter had increased to such an extent that a person standing on his left side and speaking in an ordinary tone was heard with difficulty.

On examination I found a ball of wax tightly lodged between the drum membrane and the anterior wall of the meatus. It was dislodged with some little difficulty, and upon examination was found to contain a small, white, irregular pebble, about the size of a hypodermic tablet.

Mr. L—— was very much surprised to find that he had a pebble in his ear, and for some time was unable to account for its presence. He could not remember ever having got anything in his ear or ever having suffered the slightest discomfort. He said that in summer, while bathing, he would frequently lie on the sand and let the surf break over him. We therefore came to the conclusion that the pebble must have been driven into his ear by the force of the water.

If such is the case—and it undoubtedly is—Mr. L—— carried that foreign body in his ear for over two and one-half months, as he had not been to the seashore since the latter part of July.

201 West Eighty-Seventh Street.

THE GUSANO WORM AND ITS TREATMENT.

By H. M. FOLKES, M.D.,

Panyas, Guatemala.

Claimed by the natives as being most frequent during the rainy season, found in my experience most numerous in the period just subsequent to the rainfall, the "gusano sancudo" is a most interesting member of the insect species, not so much on its own account as on that of its work. Its usual habitat is on dead trees and decayed vegetable matter in the woods. When found, it presents the body of a mosquito, having a longer head, with wavy grayish lines running down its back, legs longer than those of the ordinary mosquito, the two hind ones being quite stout. When preparing to do business, it settles upon the skin, inserts its bill, draws a little serum toward the surface, and then with a quick movement brings the tail to the point of insertion, puts it into the orifice, using the bill as a guide, and then rears upon its hind legs to insure a certain deposit of eggs. Immediately after the departure of the mosquito, gentle squeezing will produce a drop of serum from the infected point, and thus preclude the resulting worm. Left alone, the following occurs at the end of from two to three days: The orifice becomes larger and occupies the centre of a round firm swelling, which, according to Osler, resembles a boil; but in my experience the only point of resemblance is the swelling. As the worm increases in size, the swelling grows also, but not in proportion to its first appearance, for a marked peculiarity is the notable sensation of size as felt between the fingers when the worm is quite small. This is of no moment, only one is at first apt to err as to the dimensions of the worm. The symptom is usually a sharp quick pain at times. Rarely are there other symptoms, as many of my patients have been actually unaware of having a worm until informed of its presence by a comrade who happened to see it. The "it" refers to the pathognomonic sign, namely, the orifice in the top of the swelling. If there has been no manipulation of the swelling, invariably is there the orifice, which serves as ventilation; for if this is occluded, the worm dies. The native method of treatment is to tie a piece of tobacco over the opening, making the worm sick, when, in the course of several hours and after much squeezing and pressure, he can generally be gotten out. Some of the ingenious "Gringoes" hit on the idea of pasting a postage stamp over the hole. This, too, worked fairly well, but was as tiresome as the other method. Again, some have blown smoke into the hole, thus killing the larva. The method I first adopted was to cut them out; but, as most men are afraid of the knife, I set myself to discover a method at once knifeless, bloodless, and certain, and finally adopted the following, which, so far as I know, is original. With this I have never failed to get the worm, and this in the most rapid manner, on one occasion having removed fourteen in less than two minutes, this time getting five out of one hole —quite an unusual thing, for, as a rule, there is only one to a hole: After putting a little chloroform into a hypodermic syringe, I insert the point of a fine needle into the orifice and then into the body of the worm. A few drops of chloroform will paralyze the worm, which can then be squeezed out in a moment. Simply washing the wound and putting on a little piece of cotton are all the dressing required. In a few days no evidence of the former tenant can be found.

Progress of Medical Science.

The Differential Diagnosis of Ascites.—Dr. George W. Webster (*Northwestern Lancet*, November 15, 1896) gives the following points as aids to diagnosis: 1. Disease of the kidneys, either acute diffuse nephritis, or chronic nephritis with exudation (Delafield, "Twentieth Century Practice," vol. i., p. 23). 2. Cirrhosis of the liver or some obstruction to the portal circulation. 3. Organic disease of the heart with broken compensation. 4. Obstruction of the ascending vena cava from tumor, etc. 5. Obstruction of the thoracic duct. 6. Tuberculous peritonitis. 7. Cancer of any of the abdominal organs, as peritoneum, stomach, liver, pancreas, ovaries, omentum, etc.

Diagnosis of Small Ovarian Tumors.—Dr. Davenport (*Boston Medical and Surgical Journal*, 1896, No. 15) concludes an article on this subject with the following propositions: 1. Small intrapelvic growths give rise to marked symptoms. 2. Pain is usually noted, but does not bear a constant relation to the location or kind of tumor. 3. Menorrhagia or metrorrhagia is frequently present, especially in cases of cystic ovaries adherent to the uterus. 4. When uterine hemorrhage exists in connection with an intrapelvic tumor, and is not affected by intra-uterine treatment (curettage or electricity), the tumor is probably ovarian rather than uterine. Reflex symptoms are rare with small tumors, at least in the earlier stage of their development.

The Anæmia of Rheumatoid Arthritis.—Bannatyne (*Lancet*, November 28, 1896, p. 1,510), in discussing the anæmia of rheumatoid arthritis, states that it is seldom very marked except in advanced and acute cases, but in almost all, even the slightest, there is as a rule a certain amount of blood deficiency. Rarely is there extreme pallor of the skin, the patients rather as a rule presenting a sallow or brownish-yellow appearance, with moderate blanching of the mucous membranes. This sallowness is prone to pass by degrees into a deeper shade, until it insensibly merges into a distinct discoloration. Not infrequently cardiac bruits and venous hum are associated with it. Hemorrhages are rare, but not unknown. They are very rare from the mucous membranes, being most commonly seen as small purpuric spots on the lower limbs. On microscopic examination there will be found a slight though well-marked diminution in the number of red blood corpuscles, a marked and greater

diminution in the hæmoglobin, and a slight increase in the number of colorless cells. Not only does each red cell appear to contain a subnormal amount of hæmoglobin, but the coloring matter seems to be in less stable union with the cell stroma, crystallizing out more readily and being more easily acted upon by such substances as common salt, acetic acid, and sodium sulphate in solution. These changes in the blood are attributed to the action of toxins in the circulating fluid, which by their solvent action on the hæmoglobin induce the deficiency.

The Employment of Pulmonary Insufflation as a Means of Artificial Respiration in the Performance of Certain Intrathoracic Operations.—In a communication presented at a recent meeting of the Société de Biologie, Tuffier and Hallion (*Gaz. Hebd. de Méd. et de Chir.*, November 26, 1896, p. 1,131) pointed out that access to the mediastinum and to the intrathoracic organs would be facilitated if the pleural cavity could be opened while the function of the lung was maintained in its physiologic activity. These investigators have shown that the intrathoracic organs may be attacked through the pleura without inducing pneumothorax. To avoid this complication in opening the thorax and to cause its disappearance when present, it suffices to insufflate the lungs through the larynx or the trachea. If at the moment that the serous membrane is opened this insufflation is practised, the distended lungs will have no tendency to collapse. In the same way, if a pneumothorax is induced by a pleuro-parietal opening, without injury of the lung, closure of the parietal wound and aspiration may diminish the quantity of air in the pleura, but tracheal insufflation will cause its entire disappearance by causing application of the lung to the parietal pleura. The insufflation should be continued while the wound is being closed by suture. The procedure has been carried out successfully upon dogs and has been unattended with any bad effect or undesirable influence upon the pulmonary circulation. Several precautions are essential in order to secure good results. In the first place the most rigorous asepsis must be observed. The air introduced into the lungs must be as nearly sterile as possible. By this means it becomes feasible to gain convenient access to the œsophagus, the sympathetic nerve, the pneumogastric nerve, etc.

Cases in Which it is Proper to Induce Premature Labor.—1. In pelvic deformity when there is sufficient space for a seven-months' child to be delivered without injury. The object is twofold: (*a*) To save the child's life by obviating the necessity for craniotomy; (*b*) to spare the mother the dangers of craniotomy, Cæsarean section, or other operation that might be required if the pregnancy went to full term. 2. In cases in which, in previous labors, the head of the child at full term has been permanently ossified or was unusually large, so that labor has been difficult and dangerous, even though the pelvis was normal. The period of delivery need be only two or three weeks before "term" in these cases. 3. In cases in which the children of previous pregnancies have died *in utero* during the later weeks of gestation from disease (fatty, calcareous, or amyloid degeneration, etc.) of the placenta. 4. In conditions in which the continuance of pregnancy seriously endangers the mother's life—such as excessive vomiting, albuminuria, uræmic convulsions, or paralysis; chorea, mania; organic disease of the heart, lungs, liver, blood-vessels, etc., threatening fatal disturbance of the respiration, circulation, and other vital functions; irreducible displacements of the uterus; placenta prævia with hemorrhage; and in dangerous pressure upon neighboring organs from over-distention of uterus, due to dropsy of amnion, tumors, multiple pregnancy, etc.—A. F. A. King, in *Manual of Obstetrics*, p. 307.

Treatment of Backward Displacements of the Uterus.—Dr. Howard A. Kelly (*American Journal of the Medical Sciences*, December, 1896) says there can be no rational treatment without taking into consideration the causes producing the displacement. These causes are: 1. Congenital causes, due to a short vagina or to an imperfect development of the uterus, in which the retroposition has existed from childhood. 2. Retropositions developed acutely by sudden or severe strain. 3. Retropositions caused by tumors in the uterus or adnexa. 4. Retropositions, the sequelæ of pregnancies, due to subinvolution of the uterus, or to injury of the pelvic floor, or to both combined. Any given case can be properly treated by some one of the following methods (there are cases in which no treatment is required): 1. The use of a pessary. 2. Manual reposition and massage. 3. Operation upon the vaginal outlet. 4. Operation on the uterus at the vaginal vault. 5. Shortening the round ligaments. 6. A suspensory abdominal operation, or ventrofixation. 7. An operation upon the vaginal outlet and a suspensory operation combined.

The Connection between Intestinal Autotoxins and Certain Common Forms of Insanity.—Dr. Hamilton (*New York Medical Journal*, November 14, 1896, p. 646) suggests the following as possible conclusions: 1. Urines rich in indican contain very little or no preformed sulphuric acid, and are toxic. 2. When the sulphate ratio is materially changed, it is likely to indicate autotoxis in connection with an increase in the amount of combined or ethereal sulphates. 3. Such indications are generally found with acute insanities, in which rapidly developing symptoms occur. 4. Fugacious and changing illusions and hallucinations, unsystematized delusions, confusion, and verbigeration, in connection with insomnia, pallor, intestinal indigestion, constipation, and rapid exhaustion, are due to autotoxis. 5. Paranoiac states, or those in which concepts are the features, chronic stuporous conditions, and certain forms of dementia have little to do with the formation of intestinal products of putrefaction. 6. Various post-febrile, traumatic, alcoholic, or drug insanities are those in which autotoxis is most constant. 7. The variations in the excretion of combined sulphates keep pace with the changes in the progress of an established insanity, *accès* and epileptoid attacks being directly connected with putrefactive processes. 8. The most successful treatment consists in lavage, intestinal douches, gastric and intestinal antisepsis by means of hydrochloric acid, borax, salicylate of sodium, charcoal, guaiacol, or naphthalin in small repeated doses. The administration of a combination of the red marrow from the small bones, blood, and glycerin.

Traumatic Lesions of the Kidney.—Dr. Keen (*Annals of Surgery*, 1896, vol. xxiv., No. 2) advances the following conclusions: 1. The usual external disinfection should be scrupulously carried out. 2. Both for examination and for the arrest of hemorrhage, the primary wound should be enlarged if necessary. The kidney itself should be examined with great care, and it and the entire interior of the wound disinfected. 3. All hemorrhage should be arrested, of course, as quickly as possible. 4. If the kidney is unwounded, a temporary drain may be placed in the wound and the greater part of it closed. 5. If the kidney is wounded also, this wound should be sutured or a partial nephrectomy be done, followed by drainage and partial closure of the wound. 6. If the pelvis be opened, it should be sutured, if possible, and the wound drained. 7. If the large vessels are cut, or the kidney itself is

lacerated beyond the point at which it would probably retain its vitality and recover its function, immediate nephrectomy should be done. 8. If, in spite of disinfection, as a result of the primary wound, perinephritic abscess should follow, this should be widely opened and thoroughly drained, and if the kidney be hopelessly involved or the condition of the patient so serious as to demand it, secondary nephrectomy should be done. 9. If the peritoneal cavity has been entered by the vulnerating body, carrying infection in its course, and all the more if other viscera be involved, abdominal section should be done at once, the kidney treated as above indicated, and other lesions remedied. Of gunshot wounds he says that if the surgeon has reason to think that the kidney has been traversed by a ball, and the patient is in grave danger, as shown by the general symptoms of internal hemorrhage and by the physical signs of a large lumbar hæmatoma or of intraperitoneal bleeding, an exploratory operation is advisable.

Recurrent Erysipelas of the Face.—Dr. H. Lavrand (*Revue Hebd. de Lar., d'Otol., et de Rhin.*, September 5, 1896) believes that: 1. In most instances spontaneous recurrent erysipelas of the face develops from the nasal fossæ through the lacrymal duct or the nostrils. 2. The point of departure (whether from the penetration of germs or the revivication of such germs lying dormant in the tissues) is either in the nasal fossæ or, more frequently, in the more or less hypertrophied adenoid tissue of the pharyngeal cavity. 3. The preventive and also the curative treatment of recurrent erysipelas of the face consists in taking care of the nasal and naso-pharyngeal cavities, but especially in reducing the adenoid tissue in the pharyngeal vault, which appears in the form of adenoid tumors, or only in the form of granulations, which the surgeon must remove even from between the Eustachian cushions. In this manner a port of entry is removed and the too favorable soil for the culture of the streptococcus.

The Etiology of Serous Pleuritis.—Dr. A. Aschoff (*Zeitschr. f. klin. Med.*, xxix., Nos. 5, 6, pp. 440) has examined two hundred cases of pleuritis, from which he draws the following conclusions, which differ somewhat from the reports of other investigators: 1. The serous exudates are almost all free from pyogenic microorganisms. 2. Suppuration occurs after a longer or shorter period, if pus-exciters are present. The pneumococcic exudates are perhaps an exception. This is probably due to the earlier death of these microbes. 3. Such suppurative pleuritic exudates, however, can sometimes completely heal without operation. 4. The occurrence of an isolated rheumatic pleuritis is very rare. 5. The pleuritic exudates occurring in connection with arthritis acuta are almost without exception associated with affections of the heart. 6. No especial advantage can be attributed to the salicylic-acid treatment in the therapy of pleuritic exudates. 7. The so-called idiopathic exudates are almost always dependent upon tuberculosis. These may also end in recovery.

Alcoholism and Alcoholic Inebriety.—Dr. Frederick Peterson (*Journal of American Medical Association*, April 15, 1893) divides the treatment of alcoholic conditions into three categories—acute alcoholism, chronic alcoholism or alcoholic neurasthenia, and the alcohol habit. Acute alcoholism: 1. Cut off all alcohol and confine to bed. 2. Blue pill at night, followed by saline cathartic. 3. Hot wet pack for sleeplessness. 4. Hypodermatic injection of nitrate of strychnine, one-sixtieth to one-thirty-second of a grain. 5. Water, milk, kumyss, broths, soup, meat juice, raw eggs, arrow root, juicy fruits, and the like, when there is gastric disturbance. 6. In some cases bromide and chloral or duboisine are indicated. Alcoholic neurasthenia: 1. Cut off alcohol. 2. Hot wet pack for insomnia. 3. For disturbances of the alimentary canal, rhubarb and soda, hydrochloric acid, and the like. 4. Diet should be milk, eggs, and vegetable foods; meats rarely. 4. Strychnine the main agent: best given hypodermatically, but may be given by way of the mouth, in combination with quinine: fluid extract of cinchona (one-sixtieth of a grain to one drachm), or infusion of gentian. Alcoholic habit: 1. The hypodermatic injection of nitrate of strychnine, in doses above given, at least twice daily, more frequently if possible, and always by the physician himself. The moral influence and personality of the physician being of great importance, the effort and attention of the patient are thus kept at their highest pitch. 2. A diet of milk, eggs, and vegetable foods should be enforced. 3. Regular hours, occupation, and the avoidance of the society of fast companions must be insisted upon. 4. With some patients a substitute for a dram of liquor is imperative. A combination of strychnine and fluid extract of cinchona (one-sixtieth of a grain to one drachm), taken in a glass of water, works well. As it is not always convenient to carry a bottle, the following may be ordered: twenty to forty grains of red cinchona bark, one-half grain of capsicum, and three grains of powdered nux vomica, to be taken in a glass of water when required.

Hypochloruria, when it approaches the zero point in severe chronic disorders, is said by a writer in the *Journal des Praticiens* to be a sign of approaching death. Hérbert has proven it so in a number of instances in observations made upon tuberculous patients, while Huchard has cited a case of rapid death in an old diabetic when the urine no longer contained more than 0.35 per cent. of chorides, and another case of bulbar affection in which death followed closely upon the state of achloruria.

Rupture of the Quadriceps Extensor Muscle and its Tendon Above and Below the Patella.—Dr. Walker, in an analysis of two hundred and fifty-five cases of rupture of the quadriceps extensor muscle, notes the following conclusions: 1. In recent cases, in which there is not much effusion and the joint is apparently not closed, in which the separated ends can be approximated and retained by suitably adjusted pads, the mechanical treatment may be carefully considered. In the hands of the intelligent general practitioner, this method may be expected to bring about a complete recovery in the larger number of cases. From nine to twelve months will be required to re-establish fully the normal functions. 2. A too prolonged fixation in bed is unfavorable to an early recovery: therefore early massage and passive motion are strongly advised. 3. The skilled aseptic surgeon who primarily resorts to the operative method in suitable cases (but the age and vitality of each patient must be most carefully considered) may quite reasonably hope to obtain a better result in a larger number of cases and save his patient three to six months' time. 4. Catgut, kangaroo tendon, or silkworm gut should be used, and when there is much effusion drainage should also be employed. 5. When the separation is greater than one and one-half inches, or when the case has not recovered under the mechanical treatment, the operative is indicated. 6. As the length of time required for treatment is a very important consideration, so the operative method, which has diminished this period and also succeeded in a larger number of cases without increasing the danger, will be more often indicated and more frequently applied in the hands of the skilled surgeon.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHERS

WM. WOOD & CO., 43, 45, & 47 East Tenth Street.

New York, January 9, 1897.

LEPROSY CONGRESSES.

THERE is trouble among the leprologists. Those among our readers who take a special interest in this subject have probably been mystified, as we were, by the conflicting notices of proposed congresses for the study of leprosy in Bergen, London, and Moscow, and finally by the definite announcement that one would be held in Berlin, in October, 1897. We have received recently from Dr. Ashmead a circular letter which throws some light on the matter:

"During the summer of 1896," reads the circular, "the author, with Dr. Goldschmidt, started a scheme for the formation of an international world's committee, of official delegates appointed by all civilized countries, for the suppression and prevention of leprosy. It was first proposed to hold the meeting in Bergen, Norway, Dr. Hansen having claimed this honor for himself and his chief; but Dr. Hansen requested at the same time that assurances of sympathy must be obtained from leprologists before Norway issued an invitation to the congress. At that time Dr. Hansen went so far as to say that, should it be necessary, a credit would be asked from his government for the payment of a secretary, place of meeting, etc. Hansen's government finally refused to issue the call. Mr. Jonathan Hutchinson then proposed London, with the Prince of Wales as president. As soon, however, as it became known to the non-contagionists of London that compulsory isolation would be the real, the principal object of the congress, the London man's support was withdrawn. In the mean time the Berlin men, with Dr. Ehlers, of Copenhagen, at their head, were working for an independent meeting in Berlin, and they issued their call for a debate, somewhat precipitately."

The writer then continues that "no congress of mere leprologists can do any good to the lepers, by discussing what we imagine, suspect, and finally do not know about leprosy. . . . The congress proposed by Drs. Goldschmidt and Ashmead differs in every essential from the congress proposed by Drs. Ehlers and Hansen. The former represents the opinion that compulsory isolation is our only means of suppressing and preventing leprosy. The latter is a mere meeting of students of leprology, to discuss etiology, bacteriology, and cure. All that is known of these things to-day to the gentlemen who will there assemble is known to all those who will not go there. The object of our congress is the suppression and prevention of leprosy, and this object can be accomplished only by smothering it by means of isolation. We want to obtain enforced and complete isolation by the consent of governments; we want the necessary measures to be taken, everywhere, rigorously, and that the principle of isolation may pass into practice, with all its consequences, all the duties and efforts it may entail. If we succeed, that is, if our congress meets, and if the support of governments is obtained, we are sure, we know positively, that the pestilence against which we fight will be defeated and destroyed in one generation. We know it; and we challenge any man to show that there is in our hope anything too sanguine, anything exaggerated, anything that we have not a logical right to expect from our method and from our labor."

To one who is not a mere leprologist this seems unreasonable. If it is a fact which no man can deny that leprosy spreads by contagion and that compulsory isolation is the only means of suppressing it, why cannot the fact be proclaimed in Berlin in October by Hansen, Ehlers, Koch, and others, as well as in Moscow in August by Ashmead and Goldschmidt? But if there is any doubt as to the mode of spread of the disease, and there are men with a practical experience of leprosy who are not certain of its contagiousness under ordinary conditions, what can be gained by declaring the discussion closed? There is nothing so opposed to the scientific spirit as being too sure of what may not be true, as taking probabilities for facts.

"We have finally called our congress," the circular concludes, "to meet in Moscow, August 19–26, 1897, at the time of the general international congress, and we invite the men of science of Berlin and Bergen to meet with us there, and if they have a solution of the leper problem, better than ours, to produce it." We earnestly hope this warm invitation will be accepted, and we also trust that the members of the first congress will linger in the northern climes, where the air is cool, until October, and then go to Berlin and convert the heretics to the true faith. Then the world will rejoice, and if we have not learned how to cure the lepers we shall at least be agreed as to the means of escaping the disease ourselves.

PNEUMONIA.

PAPERS on pneumonia occupy the first place in the opening number for the new year of the *American Journal of the Medical Sciences*, the *Medical News*, and the MEDICAL RECORD. This is a striking evidence of the interest in the subject felt by all practitioners, but it also bears witness to the sad fact that we still know very little about the disease, or at least about its treatment.

The first of the above-mentioned articles is entitled "Certain Features in the Prognosis of Pneumonia," and is by Dr. Osler. The writer holds the modern view that the toxæmia is the most dangerous

element in pneumonia, and that the interference with respiration and the circulation is of far less importance. "Very large areas of the breathing-surface," he says, "may be cut off without seriously disturbing the cardio-respiratory mechanism. In no way is this more strikingly shown than by the condition of the patient after the crisis. On one day, with a lung consolidated from apex to base, the respirations at 60 to 65, the pulse 120, and the temperature between 104° and 105°, the patient may seem in a truly desperate condition, and it would appear rational to attribute the urgent dyspnœa and the slight cyanosis to the mechanical interference with the interchange of gases in the lungs. But on the following day the dyspnœa and the cyanosis may have disappeared, the temperature is normal and the pulse rate greatly lessened, and yet the physical condition of the lungs remains unchanged. We witness no more striking phenomenon than this in the whole range of clinical work, and its lesson is of prime importance in this very question, showing that the fever and the toxins rather than the solid exudate are the essential agents in causing the cardio-respiratory symptoms." He, of course, does not deny that there may be a gradual cutting off of air by progressive consolidation until so little breathing-space is left that the patient dies from suffocation, yet he does not regard this as a frequent cause of death. The compression of the alveolar capillaries by the exudate may also interfere with the pulmonary circulation, yet that it often does so to a fatal degree the writer is unwilling to admit. He refers to the experiments of Welch, which have shown that it is difficult to raise the blood pressure in the pulmonary artery by cutting off much more extensive areas of the circulation than are ever involved in pneumonia. He believes, therefore, that it is to the toxæmia that the excessive mortality from pneumonia is due, and his belief contains for him little that is encouraging, for he confesses that we know of no means by which we may combat effectively the poison of the disease.

The second article, on "The Management of Pneumonia Patients," by Dr. Simon Baruch, is, as the title would imply, of a more practical nature than the preceding. The writer holds the same views as Dr. Osler concerning the part played by toxæmia in the mortality of the disease, but he has much greater confidence in the result of his therapeutic measures, although admitting that the outlook in each case is very uncertain. He relies chiefly upon the effect of wet compresses, applied at a temperature of 60° F., and renewed every hour or half-hour according to circumstances; at least he dwells chiefly upon this part of his treatment, although he also gives Leaming's "sedative dose" of calomel (ten to twenty grains) at the beginning, and hypodermic injections of strychnine to spur up the flagging heart—two remedies which have been found efficacious in certain cases even when not combined with hydrotherapy. These methods, he says, "offer, at the present time, the most favorable, yet not perfect, results in the management of patients suffering from pneumonia."

With the last of the three articles above referred to, the very suggestive paper by Dr. A. H. Smith on "The Essential Nature of Croupous Pneumonia," our readers are already familiar. The method of treatment by inhalation, hinted at by the writer, like Dr. Woodbridge's plan of intestinal antisepsis in typhoid fever, is eminently logical, but the same doubt as to its practicability exists in the one as in the other. Time will prove them both, and there is hope that, in pneumonia as well as in typhoid fever, we may yet have an antitoxin upon which we can rely to save the patient in cases in which we fail (as we doubtless often, if not always, shall) to strangle the disease in its inception.

THE DERMATOLOGIST'S HARD LOT.

As though it were not enough that the cutaneous specialist must bear up under the stigma which the advertising quacks place upon the term "dermatology," and that he must see daily evidence in the public press of the increase in number and insolence of these usurpers, it would seem that new thorns are to be spread in his pathway. It is already well known that for so restricted a specialty it is overcrowded in almost all large cities. The limited field is encroached upon by the surgeon who wants all of the "operable" epitheliomata, lupus, tuberculosis cutis, and cutaneous sarcomata, and, as intimated in the annual address of the president of the American Dermatological Association at its late meeting, many of the syphilitic gummata which resemble these conditions. It has even been charged that cutting has been done in certain instances in face of the knowledge that the growth was of specific nature and could be readily cured by the iodides. No reputable surgeon could surely lend himself to such dishonesty for the mere sake of gain, so we can let that pass.

The neurologist makes inroads into the field by looking upon most skin affections as of neurotic or nerve origin, and the dermatologist would seem to play constantly into his hands by admitting such claim for many of the affections which he might just as well, or perhaps better, insist are strictly local and due to infection with micro-organisms. The nerve man lays equal claim to leprosy and the competition over a rich foreigner who comes to our hospitable shores to be cured is at times so intense that the presence of the leper is almost disclosed to the authorities.

The pediatrist treats all the children and the senectutist all the old people whose skins are ailing, leaving for the dermatologist only those of middle age who have escaped specialists in other branches.

Among the many good suggestions in the address before mentioned, there are certain restrictions as to writing which the speaker would place upon aspirants for membership and upon present members in the association, which must tend still further to aggravate the skin man's lot. "All publications representing original work, etc., should be published in a journal devoted to the specialty," while other articles "intended to teach the general practitioner" may be published in general-medicine journals, and "at no time and on no occasion should a paper be read or pub-

lished for the purpose of advertising the author." The inference must be drawn that it is not considered legitimate for a man making the diseases of the skin a specialty to have the object in view, or as one of the objects in view, in writing upon the special subjects of his branch, to let his professional brethren know that he is devoting his attention to this branch.

Would the speaker have us believe that skin specialists possess such high ideals that they can write with the view of instructing the general practitioner? Would he give it out that dermatologists differ so widely from their fellows that altruistic motives are the only ones which actuate them? The speaker might have pursued this line of thought still further and shown his hearers how far from thoughts of self all men must be who seek hospital appointments and professorships; how, impelled by a burning desire to minister to the unfortunate, or to secure a position in which they may give students the advantages of their superior knowledge, they should not fall over each other in a wild scramble for place; or how the insatiable thirst for scientific attainment for its own sake alone should prevent men from indulging in unseemly and undignified contest. He should have pointed out the wrong in seeking or even accepting a position which will tend to advertise the man holding it or make him prominent and bring him special cases. The MEDICAL RECORD believes that physicians, in common with other human creatures, are selfish. If the average man writes or lectures or holds an unsalaried hospital appointment, he does it from more or less selfish motives and for his own personal advancement, and whether he succeeds or not in getting the expected advertisement out of it depends greatly upon the quality of his work.

Such methods of letting the world know what you are doing and what you can do are legitimate.

If the colleges insist upon having the hospitals and clinics, let the men who are left out indulge in occasional use of the pen, and, if they wish to reach a large and appreciative audience, even when writing upon the most profoundly scientific questions, we say—grant them the privilege of publishing their productions in such journals as the MEDICAL RECORD.

BAD BILLS.

As an offset to the generally acknowledged abilities of the physician in every other line of his work, it is also quite universally admitted that he is entirely deficient in business tact. Whether or not he is willing to accept such a verdict from his patients, he is nevertheless at certain seasons, when bills are sent to his otherwise grateful debtors, aware of a glaring fact that there is a marked difference between actually earning his money and in being promptly paid. Often content with the sentimental side of apparent appreciation of services rendered to his patrons, of lives saved, of suffering assuaged, and of health restored, he is too easily satisfied with the reflection that he has a very noble profession but a very poor trade. All other things being equal, it is difficult to measure every standard of professional service rendered on a cold and hard money basis, and so tearful thanks and extravagant expressions of obligations on the part of his patients fill in the gaps that stretch themselves in the long waits between bills presented and checks received. There is oftentimes something extremely delicate in urging claims upon one who may owe his or her life to the skill of the medical attendant, and rather than dispel the pathos of such a recollection the real benefactor in the case is easily coaxed to lean to the weaker side of personal vanity and to square his money account with the overweighing considerations of the touching realization of human gratitude. From the purely poetical side no better compensation could be asked. Unfortunately, however, the doctor is not a mere ministering angel, who can live on air and who can rely on the usual means of aërial locomotion so inexpensively used by his seraphic brothers. He must do his flying in his buggy or sleigh, and, being deficient in feathers, he pockets the insult of neglect in the comforting folds of an ordinary overcoat. The better angel of his household, she who answers the night bell and inhales second-hand rum and onions from the other end of the speaking-tube, would be more contented with some of the wing feathers in her bonnet or warm shoes for her cherubs who have real feet. Then again, fine words do not make it easier to work your passage through the tendinous infiltrations of the tough steak supplied by the butcher patient who takes the bill in trade, nor does it help the faithful horse who contemplatively munches the cow hay from a like source, and in his own way perhaps wonders why it is so. Probably the answer may suggest itself to many a doctor who is just at this time making out his bills. The smallest amount of real gold will always outweigh the largest bulk of imaginary feathers.

MUSIC AND HAIR GROWTH.

IN a recent scientific assemblage a discussion took place upon the influence of sleep in skin diseases. One of the gentlemen who took part stated in his criticism of the paper which had been read that one might as well talk of the influence of music upon the growth of the hair. It would seem that the suggestion of a possible conection thus thrown out in a jesting way has been taken seriously. At least a correspondent of the *Temps* has made the discovery that music of certain kinds does in reality prevent the hair from falling, while that produced by certain instruments has the most disastrous effects in causing rapid development of baldness. He finds that while composers are as prone as others to lose their hair at an early age, those who play their compositions upon the piano preserve, if they do not acquire, a luxuriant growth of hair. On the other hand, wind instruments, and especially the cornet and trombone, are fatal to hirsute adornment. The violoncello and the harp keep the hair in pretty well, but the flute cannot be depended upon to preserve a strong growth after the fiftieth year of age. A number of pianists, including Paderewski, is cited in confirmation of the pronounced influence

of piano music. It has been admitted for some time that music has a certain therapeutic worth, and it will be recalled that in September last Dr. Ferrand presented a report to the French Academy on the physiological influence of music, pointing out in what ways it could be employed with therapeutic aims. Subsequently Dr. Betzchinsky reported an instance of night terrors in a child of three years, who was cured by having played to it each night music of a calming nature written in a minor key. A test was made after a few nights by omitting the music, and that night alone the child had an attack. It has not as yet been determined just what key is most favorable to the prevention of an early bald state. Probably a reasonable way of settling the disputed point would be to make a few experiments on dogs, thus proving a tolerance for different strains and avoiding the horripilation to which some patients of refined tastes might be subjected. Wind instruments are always dangerous if the hair has not a good hold, while stiff-haired people can stand anything. Possibly a good rule for any musician would be, as soon as he finds his hair falling, that he should cease playing for others.

News of the Week.

Examination for Medical Inspectors of Schools.—On January 16th, at 10 A.M., the New York City civil service commission will hold a competitive examination for the position of medical school inspector, health department. Candidates must be physicians in good standing, familiar with the clinical history of contagious diseases of children, including those of the eye, and be able to diagnose and properly isolate the same. Public, parochial, and private schools are to be examined daily, and absentees visited when necessary. Compensation, $30 per month, for ten months in each year. Applications may be obtained by addressing S. William Briscoe, secretary, New York City civil service commission, new criminal court building, New York City.

The Yellow-Fever Germ.—It has been telegraphed from Rome to London, and then from London to New York, that "Dr. Gaccarelli has discovered the germ of yellow fever and hopes to show how to combat the disease." We hope he will.

The Colored Physicians of South Carolina have a State medical society.

Dr. W. R. Gowers, of London, has been elected an honorary member of the Netherlands Society of Psychiatry.

The City Hospitals Appointments.—The following is the text of a resolution presented at the meeting of the Medical Society of the County of New York held on December 27th last:

"*Whereas*, During the year 1896, the previous board of commissioners of charities dismissed the members of the medical staffs of the City, Fordham, Gouverneur, Randall's Island, Workhouse, Almshouse, Maternity, and Nervous Diseases hospitals, replacing them by nominees of the three medical schools of this city, to wit, the College of Physicians and Surgeons, the University Medical College, and the Bellevue Hospital Medical College; and

"*Whereas*, The commissioners of charities and correction have not rectified the injustice done by their predecessors during the past year, notwithstanding that frequent and repeated petitions have been made to them so to do; and

"*Whereas*, The medical profession is satisfied that no permanent or equitable arrangement can be arrived at under the present condition of affairs, and that, if matters are left in their present condition, these positions will be a continued source of ill-feeling in the profession and of annoyance to the commissioners; therefore

"*Be it Resolved*, That it is the opinion of the Medical Society of the County of New York, as the legal representative of the medical profession of this county, that all medical positions, salaried as well as unsalaried, which are within the present gift of the commissioners of charities, be taken away from said commissioners and from the medical colleges, and be placed under the control of the municipal civil service of the city and county of New York, to the end that fitness and merit and not political nor college favoritism shall be the tests for appointment in the medical positions of the municipal service; and

"*Be it further Resolved*, That this resolution be referred to the comitia minora of the Medical Society of the County of New York, with instructions to draft a bill for presentation to the legislature at an early moment, and to consult or co-operate with any body or bodies that it may think proper, to secure the objects proposed by this resolution."

Sir Joseph Lister was raised to the peerage by Queen Victoria at the new year. He enjoys now the distinction of being the first medical practitioner who was ever called as such to the house of lords.

A Munificent Gift to Science.—Alfred Nobel, the Swedish engineer and chemist, the inventor of high explosives, has, it is said, willed his property, amounting to about $10,000,000 for a fund for the advancement of science, the interest on which will be divided equally into five prizes, to be awarded annually. Three of the prizes will be for the greatest discovery in physics, the greatest discovery in chemistry, and the greatest discovery in physiology or medicine. The fourth prize will be for the most notable literary contribution on physiology or medicine, and the fifth for the greatest achievement for the promotion of peace. The competition for these prizes will be open to the world.

A Training School for Colored Nurses.—The University Medical College of New Orleans has determined to establish a training school for negro women as nurses.

Dr. Claudius H. Mastin, of Mobile, Ala., has accepted the invitation to serve as one of the members of the American national committee of the Twelfth International Medical Congress.

Obituary Notes.—Dr. Alonzo Churchill, of Utica, died in that city on December 28th, at the age of eighty-six years. He served as surgeon to one of the New York regiments during the war of the Rebellion, and was captured and confined for some time in Libby prison.—Dr. William Wallace died at his home in Brooklyn a few days ago at the age of sixty-one years. He was born in Ireland and obtained his qualifications at the Royal Colleges of Surgeons and of Physicians. He served for a time as surgeon in the British navy and later was for several years surgeon to the Cunard steamship company. He practised many years in Brooklyn, and had been connected with the Home for Consumptives, St. Mary's Hospital, St. John's Hospital, and the Long Island College Hospital. A widow and two sons survive him.—Dr. N. W. Swords, of Lecompte Rapids Parish, La., was assassinated on December 23d, by a man with whom he had had a quarrel.—Dr. Gustave Mourraile, of this city, died at his brother's plantation in Porto Rico, where he had gone to pass the winter, on November 18th. He was born in Guadeloupe in 1823, and studied medicine in Paris, where he obtained his degree in 1854. The following year he came to New York and had since then practised here. He was prominently identified with several of the French charitable organizations in this city. A widow, two sons, and a daughter survive him.—Dr. Emil Heinrich DuBois-Raymond, professor of physiology at the University of Berlin, died in that city on December 26th. He was born in Berlin in 1818. He began studying theology, but abandoned this for natural science. After a sojourn at Bonn he returned to Berlin and studied anatomy and physiology under Jean Muller, and by his advice undertook his researches in animal electricity, on which subject he published several works. In 1868 he replaced his master as professor of physiology at the University of Berlin, and was named in 1867 perpetual secretary of the Berlin Academy of Sciences.—Dr. Byron W. Munson, of Sharon, Conn., died on January 3d, of heart disease. He was a graduate of Yale Medical School and was surgeon in the war of the rebellion. From 1881 to 1890 he was superintendent of the Soldier's Home at Noroton, Conn.—Dr. William Newman, of Brooklyn, died at his home in that city on December 31st. He was born in London, England, in 1820, received his medical education there, and came to this country immediately after, in 1845. A widow and four children survive him.—Professor Stadfeldt, the well-known obstetrician of the University of Copenhagen, died on December 12th, aged sixty-six years.—Dr. Theodore G. Wormley, professor of chemistry and toxicology at the medical department of the University of Pennsylvania, died in Philadelphia on January 3d, after an illness of several months. He was born in Wormleysburg, Pa., on April 1, 1826. He was educated at Dickinson College, and in 1849 graduated in medicine at the Philadelphia Medical College. In 1852 he was called to the chair of chemistry and natural sciences at Capitol University, Columbus, O., which he held until 1865. He was also professor of chemistry and toxicology in Starling Medical College, in Columbus, from 1854 to 1877. In 1877 he was called to the chair of chemistry and toxicology in the medical department of the University of Pennsylvania, which he had since held.—Dr. Patrick H. Bryant, passed assistant surgeon, United States Navy, died on board the training ship *Constellation*, at Newport, on December 29th, of apoplexy. He had been in the service since 1888.

New York in 1896.—During the past year there were 55,623 births in this city, an increase of 1,892 over 1895; and 41,652 deaths, a decrease of 1,767 as compared with 1895, the death rate being 21.54 instead of 23.105. There were not so many marriages by 99 as there were in 1895, but there were 16,042 more arrests by the police.

Influenza in Galveston.—It is reported that influenza has been epidemic in Galveston, Tex., during the past three weeks. The number of persons attacked is very large, but the disease is in mild form and there has been no appreciable increase in the death rate.

The Western Ophthalmological, Otological, Laryngological, and Rhinological Association will hold its next meeting in St. Louis, on April 8 and 9, 1897. The railways into St. Louis have offered the usual one and one-third fare rate to members of the association attending the meeting.

The American Physiological Society held its ninth annual meeting in Boston, on December 29 and 30, 1896.

A Memorial Statue to Dr. Parke, who was the surgeon of Stanley's expedition in Africa, has been erected at the south side of Leinster Lawn in Dublin. The statue is to be unveiled this month.

The Death Rate in New York State.—The bulletin of the New York State board of health for November shows that the number of deaths reported for the month was 7,888, which represents a death rate of 14.75 per thousand. This is the lowest death rate for years. Compared with the preceding month, in which the mortality was unusually small, the number of deaths is less by 800, and 500 less than were reported in November, 1895. November is uniformly the month of lowest mortality in the year in this State.

A Lawyer on a Physician's Diagnosis.—A referee in habeas corpus proceedings for the release of a patient in one of the State hospitals for the insane recently reported to the supreme court that the man is not insane. A physician in the hospital stated that the man was suffering from acute mania, but the referee asserted that the diagnosis of the witness was worthless.

The Pasteur Monument Fund.—An American committee has been formed to receive subscriptions to the international fund for a monument to Pasteur, to be erected in Paris. The treasurer of the committee is Dr. George M. Sternberg, surgeon-general, U. S. A., to whom contributions may be sent. We hope America will send a large subscription to honor the memory of one of the world's greatest benefactors, and we would urge every physician in the country,

after sending his subscription to the Rush monument fund to the chairman, Dr. Gihon, to send another check to Dr. Sternberg for the Pasteur monument fund. Thus will the heroes of science be honored.

The Philadelphia Pediatric Society.—Over one hundred physicians met at the College of Physicians, Philadelphia, on Tuesday, December 22, 1896, to organize the Philadelphia Pediatric Society. A constitution and by-laws were adopted and the following officers were elected: *President*, Dr. J. P. Crozer Griffith; *Vice-Presidents*, Dr. Edwin E. Graham, Dr. Arthur V. Meigs, Dr. Frederick A. Packard; *Secretary*, Dr. Alfred Hand, Jr.; *Treasurer*, Dr. C. F. Pettibone.

An Old Swindle in a New Field.—A correspondent writes: "The following trick is new, I think, and I therefore inform you concerning it, if you choose to give it publicity.

"Act 1.—A man introduces himself at my office as Dr. E. L. Adams, of Stroudsburg, Pa., talks (and talks learnedly about the throat) of sending a patient of his, a Mr. Henry Sawyer, in consultation. He then speaks of desiring to buy a spray apparatus, asks me of whom I recommend B. As the "doctor" is leaving, he asks incidentally for one of my cards. It is given.

"Act 2.—He afterward writes on my card a line of introduction to B. Presents it, saying he was sent by me, giving details. He orders the apparatus, and desires it sent to Dr. Adams, —— Street (who promptly replies by telephone, saying he knows nothing about it). Presents a check made payable to his order, endorsed by him in payment for the spray, and receives a balance in cash (in this instance $10, I believe).

"Act 3.—Check returned; no good. B. writes to Stroudsburg. No Dr. E. L. Adams and no Mr. Sawyer reside there or are known to the postmaster. I, of course, have never seen the Mr. Sawyer.

"Act 4.—The bogus and plausible representative of the medical profession has the money. The trick is, of course, capable of various modifications."

Still Another.—An old trick is being worked upon the members of the medical profession with success in several instances. A man calls at the doctor's office at a time he knows he is away. Asking for the doctor and learning he is out, the man is oh! so sorry, but may be the good doctor's wife would answer. The doctor's helpmate is summoned and is informed that the visitor is a patient of the doctor and lives (in one instance) in Newark, N. J.; he is anxious to settle a bill of $20 and asks the wife to give a receipt for that sum. The good wife, overcome both by the vision of a $20 debt being settled and also by the flattering remarks of the pleasant-mannered fellow, gives the receipt. In exchange he presents a certified check for $25, gets the $5 in change, and—well, in due time the poor doctor jots down in his account book on the credit side, "For experience, $5."

An Epidemic of Typhoid Fever.—For more than a year an epidemic of typhoid fever has prevailed at Rock Run, a hamlet of not more than two hundred persons, situated on a small stream of the same name emptying into the Brandywine near Coatesville, Pa. The first cases appeared at a small house on the hillside, and altogether forty persons have been attacked. The drinking-water of the place is obtained from springs and wells, one of which—from which the larger number secured their supply regularly and all have at times taken water—is situated in front of the village store and in close proximity to a cesspool, so that contamination is almost certain. In fact, all of the springs and wells are dangerously close to privy vaults. An investigation has been ordered by the State board of health and samples of the water have been secured for analysis and bacteriologic examination.

Epidemic of Grippe.—A dispatch from Galveston, Tex., states that over one thousand persons in that city are suffering from the grippe. Physicians are said to be overworked and druggists are kept busy filling prescriptions. There has been no marked increase in the death rate.

"New Treatment for Hydrophobia."—In a communication to a Philadelphia morning newspaper Mrs. C. E. White, president of the "Women's Branch" of the Pennsylvania Society for the Prevention of Cruelty to Animals, after condemning the Pasteur method of treating hydrophobia, proposes a "new method for both the prevention and cure of hydrophobia now coming into vogue, unattended by any cruelty to either human beings or the lower animals." The method is known by the name of its accidental discoverer, Buisson, a Frenchman, "and consists in the administration of vapor baths, accompanied by sudorific medicines, in order to remove by sweating the poison of rabies from the system." The plan of procedure is said to have been attended with much success, especially in India, where a number of stations have recently been established. A Buisson Institute has also been organized in London. Arrangements have been made for introducing and testing the plan of treatment at two places in Philadelphia, one a bathing-establishment and the other a woman's hospital.

The Meyer Memorial.—The contributions for the erection of a memorial to the late Dr. William Meyer, of Copenhagen, have reached the sum of $5,000. The fund, therefore, has been closed, since this is all that will be required for the completion of the monument, which is to be designed by a Danish sculptor.

The German Congress of Internal Medicine.—The Fifteenth German Congress of Internal Medicine will be held in Berlin on June 9 to 13, 1897. The subjects proposed for discussion are chronic articular rheumatism, epilepsy, and exophthalmic goitre.

"L'Union Médicale," of Paris, after a life of more than half a century, has ceased to appear. It was founded by Dr. G. Richelot and was edited by him for nearly fifty years. Since his death his son, Dr. L. G. Richelot, has conducted the journal, but now announces that he is forced to discontinue it because of the pressure of other engagements.

Insanity in Prisons.—It having come to the notice of Judge James Gay Gordon, of Philadelphia, that an

insane convict was confined in the Eastern Penitentiary, a commission consisting of Drs. S. Weir Mitchell, Thomas G. Morton, Charles K. Mills, J. H. W. Rhein, and ex-Judge Henry J. McCarthy was appointed to inquire into the mental state of a number of prisoners in the penitentiary. According to the report of the commission, just issued, of eight convicts examined, five were found to be insane, one of doubtful mental condition, and two not insane. The commission recommended that all but the last be sent to a hospital for the care of the insane. Two of the number were classed as belonging to the criminal insane, for whose special care regret was expressed no institution exists in the State of Pennsylvania. The six named were accordingly committed by Judge Gordon to the State Hospital for the Insane at Norristown. A commission appointed by the Harrisburg court to inquire into the alleged insanity of two prisoners at the Eastern Penitentiary from Dauphin County has reported that both are insane and has recommended their removal to the State hospital for the insane.

Italian Honors for Behring.—The King of Italy has conferred upon Dr. Behring, by virtue of his discovery of diphtheria antitoxin, the grand cordon of the crown of Italy.

Asepsis and Gallantry.—The Hungarian government permits women to study medicine if they so desire, but one of the professors at the University of Budapest has recently proclaimed that he has something to say in the matter. Of the five women now studying medicine there, one has a remarkably fine head of hair, which the professor of surgery says must come off before she can be permitted to attend his clinics. The reason he gives for his prohibition is that "wool carries infection."

A Jenner Memorial in England.—A meeting was held in St. George's Hospital, London, on December 7th, for the purpose of promoting a national memorial to Jenner. The meeting, which was presided over by Sir Joseph Lister, was well attended. It was proposed to open a subscription with the view of founding some institution in connection with the British Institute of Preventive Medicine to be distinguished by Jenner's name. There was, however, some opposition to the memorial taking this form, and it was then voted that a public meeting be called early in 1897 to consider the resolutions passed at this meeting and finally to decide the form of the memorial.

An Interesting Case is on trial in Pittsburg. By the testimony of a Dr. George T. McCord, a man secured $6,000 damages for injury from the Central Traction Company. The lawyers took $3,000 for fees, one getting $1,900 and the other two $550 each. The doctor is now suing the lawyers for a small fee, having been paid nothing, and each lawyer is trying to prove that the other one should pay the doctor's fee.—*Cleveland Journal of Medicine.*

Vital Statistics of Philadelphia.—For the week ending December 26th there occurred in the city of Philadelphia 395 deaths, of which 121 were of children under the age of five years. The whole number is 11 greater than that of the preceding week and 50 less than that of the corresponding week of the previous year. The largest number of deaths was due to the following causes: Pneumonia, 57; pulmonary tuberculosis, 42; heart diseases, 21; carcinoma, 20. During the week there were reported to the board of health 93 cases of diphtheria, 77 of typhoid fever, and 32 of scarlet fever.

Navy Department, Bureau of Medicine and Surgery, Washington, D. C. December 28th.—Assistant Surgeon L. Morris ordered to the *Essex*. December 29th.—Passed Assistant Surgeon A. R. Wentworth detached from naval hospital, Portsmouth, N. H., on relief and ordered to the *Marblehead*. Surgeon E. H. Green detached from the *Marblehead* on reporting of relief and ordered to naval dispensary at Washington, D. C. Passed Assistant Surgeon H. B. Fitts ordered to naval hospital, Portsmouth, N. H. December 30th.—Surgeon A. C. H. Russell detached from the naval medical examining board, New York, on relief and ordered to hold himself in readiness for the *Lancaster*. Surgeon J. M. Edgar detached from the *Saratoga* and ordered to the *Vermont*. Surgeon H. Wells detached from the *Vermont* on relief and ordered as member of naval examining board, New York. Passed Assistant Surgeon W. C. Braisted detached from the *Columbia* and ordered to the Naval Hospital, Newport, R. I.

Obituary.

PROF. WILLIAM H. PANCOAST, M.D.,

PHILADELPHIA.

Prof. William H. Pancoast, the distinguished surgeon, died, January 4th, at his home in Philadelphia, aged sixty-four years. He was the son of the famous surgeon, Joseph Pancoast, and was born in Philadelphia on October 16, 1835. He was graduated as bachelor of arts at Haverford College, Pa., in 1853, took his medical degree from the Jefferson Medical College in 1856, and afterward studied for three years in London, Paris, and Vienna. On his return to this country he established himself in practice in Philadelphia, and soon acquired a high reputation as a bold, rapid, and skilful operative surgeon, who was seldom mistaken in his diagnosis and was always conservative in his treatment. In 1859 he was appointed visiting surgeon to the Charity Hospital, Philadelphia, in 1862 demonstrator of anatomy in Jefferson Medical College, in 1868 adjunct professor of anatomy in the same institution. He served as a surgeon in the army during the civil war, being for the most time attached to the military hospital in Philadelphia. In 1874 he was elected to succeed his father as professor of anatomy in the Jefferson Medical College. Ten years later he obtained possession of the bodies of the Siamese twins, and demonstrated that the band by which they were united could not have been divided after early childhood without endangering their lives. His investigations, afterward published under the auspices of the College of Physicians of Philadelphia, attracted a deservedly wide interest of scientific men throughout the world. He was a voluminous contributor to medical literature and his writings always bore the evidence of sound learning and conscientious study. He became professor of the Philadelphia Medico-Chirurgical College in 1886.

Society Reports.

THE PRACTITIONERS' SOCIETY OF NEW YORK.

Stated Meeting, November 6, 1896.

ANDREW H. SMITH, M.D., PRESIDENT, IN THE CHAIR.

Some Plain Rules for Operating in Appendicitis.—DR. GEORGE F. SHRADY read the paper (see p. 37).

DR. CHARLES MCBURNEY could heartily agree with most of what Dr. Shrady had said on the various points relating to appendicitis mentioned in the paper. There were two or more on which he would make some comments. With regard to the pulse rate, the degree of pain, and the temperature, they certainly were very important. While he attached high value to the condition of the pulse, yet we must consider the stage of the disease at which this and the other points were noted. A very rapid pulse within the first twelve hours of the disease, and with a great deal of pain, did not necessarily indicate that the disease was going to be very severe. It might be very sharp indeed during the first twelve hours, and the temperature might run up very high, but he should not think that an operation was necessarily called for, although the pulse, the temperature, and the pain all had the characteristics which the author had spoken of, if it were at this early stage. A few hours later they might all have disappeared, or disappeared to a large extent. But a continuance beyond a limited time, say twelve or twenty-four hours, or an increase of these various symptoms during the whole of that time, constituted a very important indication for operation. Of course the question whether one could safely wait during so many hours, to see whether the symptoms would increase or diminish, was a question of gravity, and one which could only be decided by careful weighing of the conditions and by experience. What he wished to emphasize was that one observation of the pulse, pain, and temperature was not sufficient to determine the question to operate or not to operate.

He had to differ entirely from Dr. Shrady with regard to suppurative cases and the formation of adhesions. His experience led him to have little or no regard for the value of adhesions in protecting the patient and preserving the lesion for the more convenient and safe handling by the surgeon. He believed they did not. There was no question, however, but what adhesions were a very valuable means of separating the suppurating focus from the general peritoneal cavity. But the value of these adhesions did not increase with age. His own experience would lead him to operate in a case which he believed to be a suppurative one at the earliest possible moment, if there was no special contraindication. Trèves had laid down the rule strongly as to when one should wait for adhesions to form, and stated that the longer one waited the easier the operation would become, for with age the pus would come nearer the anterior abdominal wall. Dr. McBurney thought he was entirely wrong. The pus worked its way from the surface in a larger number of cases than toward it. Although we met with a good many suppurative cases which did come near the anterior wall, yet while waiting for this result there was a larger number of cases in which it would seek its way up toward the liver, or in some other direction away from the anterior surface, and there form adhesions which would be found more difficult to break down with age. He had never seen a suppurative case which he would not have preferred to handle as soon as suppuration took place. He could make that a general rule, unless he were to except a few odd cases, as in very fat or very old persons in whom the further course of the case showed that the abscess approached the anterior wall. Such cases, having passed through all the dangers, finally reached the surgeon when there was nothing to do but to make an incision. Then, of course, one was very glad to find that it was not necessary to open the general cavity or to separate adhesions. But that was not the question. This had to do with the course to be determined upon in the early stage. He was much more in favor of operating as soon as pus had formed, avoiding in that way all the subsequent dangers. He had not found the handling of abscesses without special adhesions to involve extra danger, for, with ordinary care in packing off the rest of the peritoneal cavity and working down to the abscess through an artificially formed funnel of pads and sponges, pus could be evacuated in all without soiling the peritoneum. That had been done repeatedly without bad results.

Regarding the statement that recurring cases did not necessarily require interference, he believed the author had given no rules by which to infer that a patient who had had one attack of appendicitis would not have another. In fact, he had not received rules from anybody which would assist him in coming to a conclusion whether a patient would or would not have a subsequent attack. He was well aware that some patients had a well-defined attack and never had another. But how were we to recognize such cases? He knew of no way in which it could be done. When a person had a well-defined attack of appendicitis he expected it to recur, and was rarely disappointed if it was not operated upon. The cases which did not recur were, in his experience, rare. The cases which had had well-defined attacks, one, two, or three, and had not been operated upon, had in a very unpleasant percentage terminated fatally; so that, taking the two propositions together, the fact that one could not define the particular case which would not recur, and the fact that a considerable number of subjects which had had one or two attacks finally had one which proved fatal, he was led to advise every patient who had had one well-defined attack to submit to an operation for removal of the appendix in the interval. He looked upon the operation done in the interval as not only very safe indeed, but as one which under modern methods enabled one to leave the abdominal walls quite free from danger of hernia—an enormous advantage over the condition left after an operation performed during the acute attack.

DR. ROBERT ABBE said Dr. McBurney had expressed his own views perfectly. The most important point which faced us, and to which attention had been directed by the author, was that of the gravity of the early symptoms, and whether the case could be operated upon to advantage at the onset, in the presence of rapid pulse, pain, and temperature. He thought most cases had some one of these symptoms pretty intense at the start. Most cases which subsided within twenty-four hours had a rapid pulse, vomiting, and pain. This intensity of the symptoms at the onset seemed to him an exact imitation of the toxin poisoning obtained when one injected the toxins of erysipelas hypodermatically. In the onset of acute appendicitis there was not always what would be taken for perforation, but rather a very quick absorption, very likely without more than an abrasion of the mucous membrane of the appendix. At any rate a very minute amount of toxic effect would give these grave symptoms within a few hours, which would subside if there had not been actual perforation. Certainly in many cases operated upon within twenty-four hours, we found that there had not been perforation, and yet there was superficial lymph exudate, etc. He there-

fore agreed with Dr. McBurney that for twelve hours at least, if the pulse rate was 120, we should give the patient the benefit of the doubt, apply ice, and wait for the subsidence of the symptoms. If any one of the symptoms progressed after twelve hours, he thought the time had come to operate.

Medical Appendicitis. — Dr. Beverley Robinson said he hesitated to discuss the subject of appendicitis, in view of the remarks which had been made, for his ideas were based upon clinical rather than demonstrated pathological facts, and he feared would not receive credence from the surgeons. There was no other organ of the body for which it could be said that in a state of disease the medical man could do nothing, and he could hardly believe that the appendix would continue to be a uniform exception to this rule. He had before expressed very strong personal convictions regarding recurring cases of appendicitis, to the effect that they were sometimes of rheumatic origin. His reason for believing this was clinical experience and the fact that the appendix bore a close relation in structure to the tonsils, which were known frequently to take on rheumatic inflammation. Such inflammation was not necessarily suppurative, and he did not believe but that there might be appendicitis without suppuration demanding surgical interference. He had in mind one case, within a stone's throw of the present meeting, in which during a second attack a distinguished surgeon said he would have operated had he seen the patient twenty-four hours earlier. As it was, she recovered without an operation, and having since visited the Hot Springs and others, and taken antirheumatic precautions, she had gone five years without another attack of appendicitis. The rheumatic tendency had shown itself in the joints, etc. He had certainly seen salicylates do a great deal of good, and in some instances they had enabled him to get along without calling a surgeon. He had seen the appendix removed in several instances when it showed nothing but inflammatory signs, which could be accounted for on no theory more plausible than that of rheumatism.

Dr. McBurney would be very sorry indeed to see it stated that this society indorsed the rheumatic theory of such a serious disease as appendicitis, a theory which, so far as he knew, had no basis. The mere fact that a patient recovered from appendicitis after taking a given medicine need not justify the indorsement of that medicine for appendicitis, for we frequently saw patients recover who might have had salicylate of sodium or anything else. The grave objection to having this theory go out with the indorsement of a professional society was that there was a strong tendency among practitioners in the country, who were either inexperienced or without aid, to search anywhere and everywhere for means to avoid the real treatment. A statement from New York that salicylate of sodium was useful in appendicitis would lead to its use in very many critical cases for which there was no hope except in a timely operation. He had himself removed the appendix frequently, and he had not seen anything in the lesions—which were always well marked—which could be accounted for upon the theory of rheumatism. We had to account for an actual pathological lesion. There was in almost every case —indeed, he was almost prepared to say without exception—some form of obstruction to the escape of the contents of the appendix into the intestine. That had nothing to do with rheumatism.

Dr. Shrady remarked, in closing the discussion, that Drs. McBurney and Abbe had misunderstood what he had intended to make plain. Of course, he did not mean to say that the mere elevation of the pulse or temperature, or increase of pain as evident in a casual examination, were sufficient to advise immediate operation. The very transient condition of these phenomena was indeed an argument in favor of waiting. It was of the greatest importance to make a study of the phenomena and not be in a hurry to arrive at a conclusion. The whole thing, as Dr. McBurney expressed it, was in the proof that the symptoms named continued to manifest themselves in a progressive way, and of course time was required to settle these points. In regard to the suppurative cases, in one sense he entirely agreed with the opinions of Dr. McBurney; at the same time he did not believe it was wrong to watch and wait for a day or two longer while an abscess was forming, in order to be the better prepared to run the risk of breaking up imperfectly formed adhesions. He was, in fact, speaking more for the practitioner away from large cities than for such as were well prepared to meet the complications and emergencies of such cases. An operative case in the country was very different from one in a large city, with its plentiful resources of skilled work. In this respect in an ordinary case it reduced the chances of bad result with the younger operator. Personally, he always operated when an abscess existed, as with abundance of skilled assistance he had found it comparatively safe, especially when the peritoneum was guarded against infection by the methods so well demonstrated by Dr. McBurney.

Only the day previous Dr. Shrady had operated in such a case in the practice of Dr. St. John, of Hackensack, N. J. In that instance the case belonged to the irregular ones. The cardinal symptoms of pulse rate and temperature were negative, and the pain was of a very ordinary character. The only portentous symptom was vomiting. He differed from Dr. McBurney in always advising operation after recovery by other means from a first attack. He was always willing to wait for a second one before deciding, and had never had cause to regret such a course. His judgment had been influenced, perhaps, by experience, notably in two cases. One of these was that of a farmer, near Dr. Shrady's country residence. That patient had a well-marked and severe case of appendicitis twenty years since, was still alive, and had never suffered from the slightest inconvenience. At the time of the attack Dr. Shrady advised an operation, and the patient every time he had an opportunity of answering questions took occasion to remind the doctor of a lucky escape from the knife. The other was the case of a well-known medical gentleman of this city, who had four distinct attacks of appendicitis, in one of which he was seen by Dr. Shrady, and on which occasion the diagnosis was confirmed by the late Professor Loomis. The patient declined operation, died of another disease, and at the autopsy no lesion of the appendix was discovered. There were often circumstances in a case that militated against an operation. They occurred to every practitioner. The paper was intended to challenge discussion from such a conservative basis.

Anal Fissure.—Dr. Sims (*North Carolina Medical Journal*, November 5, 1896) says that in recent cases a cure can often be effected by keeping the fæces soft by laxatives and enemata, washing out the rectum with carbolic acid or other antiseptic solution after each evacuation, the application of silver nitrate and some antiseptic powder or unguent to the ulcer. When this fails, the next best treatment is to paralyze the sphincter by stretching it with the thumbs. Complete anæsthesia is required for this operation. Another method is to make an incision through the base of the ulcer, dividing either the whole or a portion of the sphincter. Any small tab of mucous membrane or polypoid growth complicating the fissure should be removed at the time of the operation.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON GENERAL SURGERY.

Stated Meeting, December 14, 1896.

B. FARQUHAR CURTIS, M.D., CHAIRMAN.

Tuberculosis of the Kidney.—DR. FRED KAMMERER presented a young woman, whom he had first shown to the section six years ago after removal of the left kidney for tuberculosis. Before that she had had suppuration of the cervical glands, and three months prior to removal of the kidney he had evacuated a lumbar abscess, evidently connected with the kidney, which he removed as soon as the patient was able to withstand the operation. The right kidney seemed to be healthy. A sinus remained until eight months ago, until which time the patient remained well, but when the sinus closed the lymphatic glands in various parts of the body enlarged, and the remaining kidney could now be felt double its normal size.

Dr. Kammerer presented a tuberculous kidney from another case, that of a girl, fifteen years of age; family history negative; personal history negative, patient having been well until three weeks before he saw her, when pain developed in the left side; there was elevation of the temperature; a fluctuating tumor formed in the lumbar region, which he incised and evacuated pus. At that time the kidney was not recognized, but three months later—the sinus persisting—he reopened the wound and enucleated the tuberculous kidney. There was no other tuberculous focus, and the patient was still well.

In the first case the tuberculosis of the kidney seemed to be secondary; in the last one it seemed to be primary. Examination of the urine yesterday of the patient shown revealed no evidence of tuberculosis of the remaining kidney, although the increase in size would point to its involvement.

Plastic Operations on the Lip and on the Face.—DR. C. N. DOWD presented a man whose lower lip he had removed for epithelioma a year ago. There had been no recurrence, and the cosmetic effect left by Malgaigne's method of closing the gap had been perfect. The scars were scarcely visible. The glands below the inferior maxilla, including the submaxillary, were removed.

Dr. Dowd's second case was one of small epithelioma of the cheek, removed five years ago. The gap was filled by sliding in of the skin in such a way as to leave no deformity, and no recurrence had taken place. There was now a little nodule beneath the skin, scarcely perceptible to the touch, yet exciting some suspicion.

Tuberculosis of the Knee; Arthrotomy.—DR. R. A. SANDS presented a boy who two and one-half years before had fallen, and ever since had suffered from tuberculosis of one knee. It had been treated by apparatus, but got worse, and when he saw the boy, last August, he proposed arthrectomy to the father, but was permitted only to make two small incisions, through which he introduced a spoon and removed what tuberculous material he could. It was evident, however, that not all was reached, yet under packing with iodoform emulsion the wound rapidly healed. There was ankylosis, but no pain and no local temperature.

Exophthalmic Goitre Treated Successfully with Thyroid Extract.—Dr. Sands also presented a young woman who had come to him in September, this year, for œdema of a lower limb and headache; and it was in looking for a cause of these symptoms that he found enlargement of the thyroid, some exophthalmus, and a pulse of 128. Under the use of thyroid extract all the enlargement of the thyroid gland had disappeared; all the symptoms had disappeared except some tendency to increased frequency of the pulse under excitement. Usually it was not above 80.

Old Irreducible Dislocation of the Humerus; Arthrotomy.—DR. J. P. TUTTLE presented a man whom he had seen in September, two months after subclavicular dislocation of the humerus. He had no use of the arm whatever. Attempts at reduction were made under ether, but as soon as the head of the bone was brought nearly within the glenoid cavity, something would act to pull it back to its former position. He then cut down and found that the head of the bone had passed around the coraco-humeral ligament in such a manner that when it was brought nearly within the glenoid cavity the ligament would jerk it out like the string of a bow. Reduction was easily effected on replacing the ligament. The man now had good use of the arm.

Extensive Skin Grafting of Arm.—DR. A. L. FISK and DR. ROBERT ABBE presented a case of extensive skin grafting of the arm, forearm, and hand, and also various fractures, etc., with radiographs. The case of skin grafting was that of a woman who had sustained a burn over a year ago, which involved the whole arm to the shoulder, and had left the skin hanging in shreds from the wrist to the elbow. After some months grafts were taken from the thigh to cover the forearm. The operation was discontinued at this point on account of the low condition of the patient. These grafts grew, but subsequently some which were implanted on the arm failed. Her health was poor; she suffered much pain in the arm, until one day it occurred to him to give iodide of potassium. The pain then ceased, the granulations took on a healthy appearance, the grafting was completed successfully, and the patient was shown in illustration of the excellent results. The elbow, which before promised to be permanently helpless, now had all of the normal movements, the skin was supple, and the patient had an entirely useful limb.

Various Fractures, with Radiographs.—The series of radiographs presented by Drs. Fisk and Abbe illustrated fractures of the upper and lower extremities at various points; also a biliary calculus, an enterolith, a tumor of the lower third of the humerus, presumably malignant, etc.

Laryngeal Stenosis (Cicatricial) Treated by Intubation.—DR. JOHN ROGERS presented a young woman, who had come to the hospital with acute œdema of the larynx and cicatricial contraction, extending from the thyroid cartilage to the entrance to the trachea. There was a history of syphilitic infection in 1894. He tried intermittent dilatation, but failed to pass the intubation tube, then did tracheotomy, and later, after one failure to pass the intubation tube while the tracheotomy wound was open, succeeded when this had healed. The tube became plugged on November 25th and had to be removed, but the larynx collapsed and it was reintroduced.

DR. A. M. PHELPS, speaking of Dr. Sands' case, expressed the opinion that in children under twelve, suffering from tuberculous knee, an apparatus should be applied, protecting the limb but permitting them to go about. If the condition progressed, arthrotomy should be done. After the twelfth year excision gave the best results. He had performed excision seventy-one times, without a death.

DR. HERMAN MYNTER, of Buffalo, differed from Dr. Phelps, for he believed there was a focus of tuberculous disease in the bone, either in a condyle or in the tibia, and unless this were removed there would be recurrence. It was only in a minority of cases a synovial, not a bone affection.

DR. PHELPS said he would try other treatment for six months, and seek to spare destruction of the joint by operation.

Dr. Mynter replied that he would remove the focus of disease in the bone, and thus prevent it from spreading to and destroying the joint.

Dr. Sands agreed with Dr. Phelps. If he were a child he would not want his knee-joint gouged into until there was evidence that it contained tubercles.

Dr. Abbe remarked, regarding skin grafting, that the tendency to contraction was obviated by removing granulation material before grafting.

Fracture at the Ankle.—Dr. A. M. Phelps presented radiographs of a case of fracture of the internal and external malleoli, in which the pictures alone enabled him to make the diagnosis of the exact condition and how to repair it without unnecessary surgery.

Early Diagnosis and Early Nephrectomy for Tuberculosis of the Kidney.—Dr. Willy Meyer read the paper. One patient was shown, and one or more tuberculous kidneys were exhibited. On some points he quoted from his paper read at the last meeting of the State Medical Society on the early diagnosis of tuberculosis of the kidney. The following case illustrated some of the points which he wished now to emphasize. A woman entered the hospital, giving a history of frequent micturition, lancinating and burning pain during micturition, pain in the pelvis, headache, insomnia, urine slightly turbid. She was sent to his ward, and in accord with his custom he had a careful examination made, and no evidence was found of tuberculosis of the lung or elsewhere, and yet cystoscopic examination revealed a slight change in the bladder, which convinced him that there was probably tuberculosis of one kidney. About the mouth of the right ureter was an appearance as of footprints in snow, and at the orifice was slight congestion. The rest of the bladder was normal. Introduction of the ureteral catheter revealed some constriction, about three-fourths of an inch from the orifice. An attempt to collect the urine from the right ureter failed, but succeeded with the left one. The urine thus collected was clear, whereas that passed by the urethra contained tubercle bacilli, which it was fair to infer came from the right kidney. The diagnosis was then made of primary tuberculosis of the right kidney, with secondary local infection of the bladder. Nephrectomy was then performed; the kidney (the right one) was tuberculous. The patient made a good recovery; the symptoms disappeared, the tubercle bacilli disappeared from the urine, and the tuberculous spots about the right ureteral orifice disappeared.

A case almost exactly similar had been published by Caspar, of Berlin, the only difference being that Caspar was able to catheterize both ureters. Dr. Meyer had seen other cases, but later in the disease. The one related belonged among the very few thus far reported showing what could be done to prevent secondary infection when early diagnosis, leading up to nephrectomy, was made. He impressed the necessity for cystoscopic examination in all cases of obscure bladder or urinary troubles. While in the majority of cases calculi might be the cause of the symptoms, yet in some tuberculous trouble would be found.

The chairman, Dr. Curtis, remarked that in women Kelly's cystoscope could be used by one not specially expert. The fact that the localized bladder changes had disappeared so promptly in Dr. Meyer's and the other cases referred to, would seem to indicate that it was due only to irritation, and had not yet resulted in true tuberculous infection.

Dr. F. Tilden Brown had had opportunity in two autopsies to verify the existence of a local congestion around one ureteral orifice, the side on which there was tuberculosis of the kidney. It was very fortunate that Dr. Meyer had met with such a case in time to operate and prevent secondary infection. He would prefer to use the term local to that of primary infection of the kidney, for it was difficult to conceive of the bacilli reaching the kidney primarily. Tuberculosis might exist in the kidney for a variable period of time without evidence of it being found in the bladder or urine, this evidence appearing only after communication had become established with the pelvis of the organ. Even if one operated as soon as urinary and vesical symptoms developed, he might then find the kidney practically destroyed. He mentioned two cases of general tuberculosis, in which lesions were also found in the kidney, evidently of a chronic nature. In one at least he thought the patient might, as far as the kidney lesion was concerned, have lived on indefinitely under a change of climate and correct diet. While he regarded Dr. Meyer's position as correct, and thought that in time many cases might be saved by early diagnosis and operation, yet too rash interference was to be avoided, for no doubt there were cases of commencing or limited tuberculosis of the kidneys, as of other organs, from which the patient might recover. If, after six months' climatic and hygienic treatment, one found the patient declining, he should operate.

Dr. Mynter, of Buffalo, congratulated Dr. Meyer on his pioneer work in cystoscopy and the diagnosis of kidney disease, in this country. He repeated the opinion expressed while discussing Dr. Sands' case of tuberculosis of the knee, that one should remove a tuberculous focus as soon as he established the diagnosis. He would likewise remove the tuberculous kidney. He mentioned a case in which the cystoscopic examination alone could, and did, reveal a piece of chewing-gum in a man's bladder, the patient having introduced it into the urethra to determine whether he had stricture. He also mentioned a case in which a large cast came down from one ureter; the diagnosis of tuberculous nephritis was made, nephrectomy was done, and the patient's symptoms disappeared.

Dr. Meyer closed the discussion.

SECTION ON GENERAL MEDICINE.

Stated Meeting, December 15, 1896.

R. W. Wilcox, M.D., Chairman.

Mucous Colitis, a Functional Neurosis.—Dr. Walter Mendelson read the first paper. Under the term mucous colitis (and numerous synonyms) there had been known for three hundred years a complex of symptoms which deserved to be more generally recognized by the profession at large than it was. The condition existed in various degrees of severity in many patients—in neurasthenia, chronic dyspepsia, and other troubles. Confining himself chiefly to his own observations, the author said there were three cardinal symptoms which were so characteristic as to be pathognomonic. They were neurasthenia, mucous passages, and abdominal pain. These three symptoms were not always present to the same degree nor at the same time. Some one might be so slight as scarcely to attract attention. Another marked feature was chronicity. The attacks were usually brought on by nervous strain. The mucus was usually in the form of flat or round cords, often a foot or more in length, but might appear in flakes, in balls, etc. There was usually some tendency to diarrhœa. Few cases came under the physician's care which had not been treated for a variety of supposed causes, but usually for an inflammatory condition of the intestine or nervous dyspepsia, the latter thought to be secondary. It occurred oftenest in women at the childbearing age, seldom in children; old age was almost exempt. Of the pathology we knew nothing, as the disease was never fatal. Dr. Mendelson regarded the bowel trouble as but one of the many disturbances of the nervous function, whose

totality was summed up in the convenient term neurasthenia. It might be regarded as the metabolic product of glands whose particular nerve apparatus had become involved in the general nervous disturbance. Treatment naturally resolved itself into the treatment of the obscure causes of neurasthenia. The plan which had given him the best results was the rest cure, combined with irrigation of the bowel. He told the patients that if they would follow his instructions and he could manage to increase their weight ten pounds, they would be cured, and usually it so happened. Persistence and patience were required. Milk diet was important, but not sufficient alone. The bowel was irrigated twice a day. Incidental points were brought out in several cases related.

Dr. Charles L. Dana opened the discussion. He had heard only a part of the paper, but thought it probable his views coincided with those of the author, that while mucous colitis often occurred in neurasthenic people, yet it was not always so, and in some instances the neurasthenic state seemed secondary. Where it was primary he thought it might act only in bringing about a state in which the germs which constantly infested the intestine had opportunity to produce more or less inflammation, which he supposed existed in some degree in these cases. Why mucous colitis should be present in women oftener than in men was a fact which he could not explain, for neurasthenia occurred oftener in men. The prognosis as to permanent cure was bad.

The discussion was continued by Drs. M. Putnam Jacobi, Morris Manges, Max Einhorn, Leonard Weber, and the author closed.

Purpura Hemorrhagica.— Dr. Leonard Weber in this paper cast a general view over the subject of purpura hemorrhagica, and then read the histories of three cases, two seen in his own practice, one in that of another physician. The first patient, a strong man, had had a slight attack of purpura, accompanied by rheumatoid pain, six years before. He had also glycosuria and some varicose veins. The attack of purpura seen by Dr. Weber had followed indiscretion in eating and drinking. The purpura spots multiplied until they existed over the back and various portions of the limbs and body, also on the mucous membrane of the mouth. The urine contained six per cent. sugar, but eventually the sacchaine matter fell to less than one per cent. It was some weeks before the spots disappeared. His second case was that of a servant girl, aged twenty-four, second attack. There was a bad condition of the teeth and the gums bled. After excluding malaria, he thought the condition of the teeth might have given rise to toxins, on which purpura possibly depended. The third case referred to was shown before the German Medical Society by Dr. Moschcowitz, and illustrated the danger of a patient exposing himself too soon after improvement or disappearance of the hemorrhagic spots. The man went out to the baseball ground, and while there was stricken by hemorrhagic pneumothorax. He gave a history of frequent attacks of gonorrhœa. The three patients recovered. Dr. Weber thought purpura of different forms and passing under different names was of one kind but of different degrees.

Dr. S. S. Burt opened the discussion. He had always looked upon purpura as one disease differing in degree. In treatment he had relied upon improving the nutrition, but he had had no severe cases. In 1883 a writer claimed to have found a germ associated with purpura, but he did not classify it.

Dr. C. C. Ransom had frequently seen in children purpuric spots associated with urticaria. He was inclined to believe that purpura, developing upon urticaria or skin eruptions and following fevers, belonged to one category, while purpura hemorrhagica belonged to another category. Purpura hemorrhagica, as described in the text-books, was by no means a simple disease, for in a large percentage of the cases collected by Dr. Lockwood the subjects had died. Dr. Ransom had seen two cases, both of which were fatal. He regarded it as an infectious disease.

Dr. Hollis had hoped to hear more definite proof of the infectious theory. All anæmias were liable to be attended by hemorrhages. He saw no reason to believe a dyscrasia might not be at the basis of purpura.

Dr. Richard Van Santvoord remembered a case in which hemorrhagic eruptions disappeared upon stopping considerable doses of quinine.

Dr. Morris Manges related three cases of purpura hemorrhagica, which, he said, effectually proved the infectious origin of the condition, as suggested by Dr. Weber. Recurrent attacks had taken place and were rebellious to treatment, until he directed his attention to the throat. The eruptions disappeared with cure of quinsy sore throat.

Dr. Weber closed.

Dr. H. Newton Heineman demonstrated instruments of precision used in the observation of cardiac disease.

SECTION ON GENITO-URINARY SURGERY.

Stated Meeting, December 8, 1896.

William K. Otis, M.D., Chairman.

Urethro-Rectal Fistula.—Dr. J. P. Tuttle presented a man showing the result of an operation which he had performed to close a urethro-rectal fistula. There had been for some reason a sloughing of the tissues, which left an opening as large as his thumb in the prostatic portion of the urethra, connecting this with the rectum, three-fourths of an inch from the margin of the anus. All the urine poured into the rectum, and there was a great deal of irritation. He performed a preliminary colotomy, then dissected out the cicatricial tissue of the cavity constituting the fistulous connection, closed the opening in the gut, made an opening at a lower point in the urethra, inserted a catheter for bladder drainage, and left the original opening in the urethra to heal by granulation. It was his intention to leave a perineal opening for bladder drainage, but union had taken place more rapidly and completely than he had expected, so that only a few drops of urine escaped during straining. He thought the urethral fistula closed more smoothly in these cases when allowed to heal by granulation than when the edges were united by suture.

Drs. Eugene Fuller and F. Tilden Brown related somewhat similar cases.

Tuberculous Epididymitis.—Dr. Eugene Fuller presented a specimen consisting of the testicle and the scrotal contents of one side, removed from a young man with a tuberculous history and some pulmonary signs, and in whom tuberculous epididymitis had been lit up by an attack of gonorrhœa about three months before he operated. When he first saw him the tumor of that side of the scrotum was about the size of a cocoanut; the tissues were infiltrated and angry looking. Previously, some one had attempted to treat the case as one of ordinary epididymitis by use of the Paquelin cautery, and had caused two great sloughs on the surface of the scrotum. Dr. Fuller hoped by operating to keep the man from becoming bedridden, but in private cases of persons of means he thought he would not have operated even in such extremity. At first he removed only the thickened tissues and left the testicle, but next day removed the latter also, lest it should delay healing. He had never before seen a case with such rapid tuberculous infiltration of the tunica.

Prolapse of Glans Penis through a Preputial Opening.—Dr. Guitéras related a case in which the glans penis prolapsed through an opening in the prepuce made by chancroidal ulcer, and in which he relieved the strangulation by doing circumcision.

Double-Current Rectal Irrigator and Prostatic Cooler.—Dr. Robert C. Kemp showed the instruments and spoke of their general use in connection with diseases of the intestine and of the prostate. Some older instruments which could be utilized for these purposes were also shown, but the one which he had found to fulfil the purpose best he had devised at the suggestion of Dr. William H. Thomson as to the need of such an instrument. It consisted of an outer tube, with one or two side perforations for the return flow, and of an inner tube, screwed into the distal end of the outer one, for the entering current from the fountain syringe. The material used was hard rubber, but might be of glass, and was somewhat modified for cooling the prostate. Soft-rubber tubes and bags were not sufficiently good conductors of cold. By attaching a Y-tube, one arm connected with hot, the other with cold water, one could get the effect of alternate use of hot and cold—an idea suggested to him by Dr. Minor. Rectal irrigation was indicated and practised by this means by Dr. Thomson and Dr. Delafield in colitis, for cleansing purposes, for diuretic purposes, etc. Dr. Grandin had thus injected many gallons of salt solution in cases of eclampsia. The prostatic cooler was indicated in prostatic irritation, congestion, and some other conditions of this and neighboring organs.

Dr. R. W. Taylor expressed his intention to use the prostatic cooler, believing that it would be of value in certain troubles of the prostate.

Dr. William H. Thomson said he had for years observed a nervous connection between the stomach and rectum in disease of one or the other of these portions of the alimentary tract, and the need of an instrument like that devised by his friend, Dr. Kemp, was based not alone upon the local effect of irrigation, but also upon its reflex action. He spoke at some length upon its action in dysentery, in fevers, its diuretic effect by close proximity to the kidney as well as by absorption of the injected fluid, etc. It was also a means of acting upon disease of the central nervous system, for recent histology had shown that the axis cylinder was an actual part of what formerly was spoken of separately as the nerve cell, but now was recognized as only a part of a whole called the neuron.

Dr. P. A. Morrow inquired whether the speakers had observed any influence upon the general temperature. Some years ago he had used the rectal cone in treatment of hemorrhoids, the patients had complained of the cold, and on taking the temperature he had sometimes found it subnormal. It was known that the hot dry-air treatment of joints caused an elevation of the general temperature.

Dr. Thomson replied that he had made no thermometric observations.

Dr. James P. Tuttle said that he was gratified at the interest shown in this method of irrigation, although surprised that any one should consider it new. It had been used for nearly a century in the treatment of diseases of the rectum and sigmoid. The instrument exhibited was almost identical with one devised by himself in 1886, and which itself was a modification of Skene's irrigator. In 1889 he had read a paper upon this subject, and had exhibited the instrument before the surgical section of the academy, in connection with a paper on hemorrhoids, and had published a cut of it in Morrow's "System of Genito-Urinary and Cutaneous Diseases." He had described its application to genito-urinary affections in a paper on "The Rectum and Urethra as Related in Disease," published in the New York *Polyclinic*, in 1894, and had again referred to it in the same journal in a paper on "The Rectum and Female Reproductive Organs as Related in Disease," published during the present year. He had made use of the instrument almost daily for the past ten years, and could corroborate almost everything Dr. Kemp had said with regard to it. He had also made some experiments on a colotomized patient, and proved to his own satisfaction that the current did ascend the descending colon and maintain its temperature almost entirely. His instrument, he said, had been favorably received by a large number of the profession throughout the country, and he had received the most gratifying testimonials as to its benefits. He thought, however, that the value of the method was greatly enhanced by using it, in connection with the long Wales bougies, to dilate contractures and straighten out the folds of the sigmoid, and with the sigmoidoscope to diagnose and treat localized ulcers of the lower bowel.

The Detection of Stone in the Bladder.—Dr. Willian K. Otis read a paper on this subject. Ordinarily the detection of stone in the bladder was an easy matter, but sometimes the most skilful surgeon failed to recognize even a large one. The first symptom mentioned was pain in the perineal region, radiated to the prepuce, sometimes in the thighs or elsewhere, variable in severity, worse on severe exercise, sometimes entirely absent on lying down, severe at the conclusion of micturition; frequency of micturition, sometimes dribbling only, because of partial obstruction from the stone lying at the internal orifice of the urethra; cystitis in greater or less degree; hemorrhage. The microscope might show particles of stone in the urine which the unaided eye failed to detect, and point out the composition of the stone. But these symptoms might exist without a stone being present, and they were exceedingly variable in degree, so that other methods were necessary to establish the diagnosis. The most important of these was the use of a metallic sound, which gave a click when it came in contact with the stone. The one most commonly used was that originally devised by Sir William Thompson in 1860. But Thompson himself had modified this, and it was this modified instrument, still further modified by Dr. Otis by making it hollow, so that it could be used as a catheter like the original Thompson instrument, which the reader now used. The advantage of weight was obtained by inserting a solid stylet when not using the instrument as a catheter. The distal end was somewhat flattened so that it would not roll off of the stone too readily. The proximal end or handle was composed of a round and a flat portion, the former corrugated, the latter roughened on one side. Sounding-boards attached to the handle were not an advantage. The small lithotrite was the best instrument for taking the diameter of the stone.

Dr. Otis spoke of the tendency of stones to hide themselves behind the prostate, or anterior to the urethral opening, and to become sacculated. When exploratory incision became necessary, he advised suprapubic cystotomy, as the advantages which it possessed over a perineal opening far outweighed the slight risk. He also spoke of the cystoscope and the Roentgen ray. Uric-acid stones were not so opaque as the bones through which the Roentgen rays had to pass, and consequently could not be thus detected. Some oxalates could be thus detected, but it was phosphatic stones which were most opaque to the rays.

The discussion was participated in by Drs. Bangs, Fuller, Brewer, and the author.

Hysteria.—Treat the attack by mechanical irritation of the pharynx and nasal mucous membrane or by violent cutaneous excitation.—Clozier.

MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

Stated Meeting, December 28, 1896.

LANDON CARTER GRAY, M.D., PRESIDENT, IN THE CHAIR.

The Presidency of the Board of Health.—In the report of the *comitia minora*, it was recommended that steps be taken to have a hearing before the commission on the charter of the Greater New York, and urge that the new charter not only do away with the present discrimination against the medical profession in not permitting a doctor to hold the office of president of the health board, but that it make it obligatory to appoint a doctor to that position. After some discussion, participated in by DR. WARDEN and others, a resolution offered by DR. J. P. TUTTLE was adopted, empowering the president to appoint a committee of five to appear before the charter commissioners and urge upon them the importance of not discriminating against physicians as officers in the new organization of the Greater New York. Later, the president appointed Drs. Tuttle, Fisher, Brill, Murray, and Lewis.

Methods of Typhoid Bathing and an Analysis of the Result in Two Hundred Cases.—DR. J. P. THORNLEY read the first paper of the evening. It was based on 230 cases of typhoid at the Presbyterian Hospital, 1893–1895. Of this number 200 received the bathing treatment in some form, 48 of them the tub bath alone, 26 of them sponging alone. In describing the tub bath, friction by the hand of the nurse was mentioned as an important factor. The bathtub was narrow. It was rolled to the bedside and the patient was lowered into it by three persons. The extremes of the water temperature were 90° and 60° F. The patient was kept in the bath fifteen minutes, but in some instances a shorter period with a lower temperature was better than the full period with a higher temperature. The cases were analyzed with reference to the period of admission, stay, method of treatment, relapses, mortality, etc. Thirty-eight were admitted the first week of the disease—mortality, 7.8 per cent.; duration five weeks; 112 were admitted the second week—mortality, 7.4 per cent.; stay nearly six weeks; 38 were admitted the third week—mortality, 18.9 per cent.; stay seven weeks. Of the 48 who received the full bath alone, 3 died. Of 26 who were simply sponged, 4 died. When both tubbing and sponging were used, because of some special feature in the case, the mortality was about 13 per cent. The mortality for the whole number, irrespective of the method of bathing, was about 8 per cent. Up to the fourth week the percentage of complications was greater the later the cases were admitted.

Tub Treatment the Best Routine Treatment.—DR. W. P. NORTHRUP opened the discussion. Most of the cases mentioned in the paper had entered the Presbyterian Hospital during the months of his service. He believed the tub treatment of typhoid was the best for routine treatment. In the severe cases which had entered the hospital, it was the one thing which had done much to carry the patients comfortably through their sickness. He did not mean to say, however, that the tubbing was actually going to save the lives in a large percentage of severe cases. But it was urgently demanded, because it helped such patients to traverse pretty comfortably the weeks of continuous fever and made the prognosis better. He had seen mild cases get along well under sponging. But observers of epidemics could give us points which could not be squeezed out of hospital records, and he hoped those who had witnessed the Stamford and other epidemics would give their experience.

Experience at Roosevelt Hospital.—DR. W. H. THOMSON had seen sixty-one cases of typhoid fever in his service at Roosevelt Hospital in the fall of 1895 and 1896. Five of these subjects had died. One of these had lobar pneumonia when admitted; one died apparently of syncope after the typhoid ulcers had healed; three were admitted the third week, were delirious, and remained delirious until death. But in judging of the value of any treatment, the question of greatest importance was, what was the condition of the patient during the course of the sickness? Of the 61 subjects, only 11 were delirious, and 5 of these were delirious on admission. Number of cases of tympanites, 9; relapses, 4; hemorrhage, 4; no subsultus tendinum, no dryness of the tongue, no sordes. This absence of the classical symptoms of typhoid, as it was seen formerly, was attributed to the tub treatment and intestinal antiseptics. The patient was put into the tub as often as the temperature rose to 103° F. Every patient was given, every third night to the middle of the third week, five to ten grains of calomel with thirty-five grains of compound jalap powder; also, for every twenty-four hours, ten grains each of saccharated pepsin and subnitrate of bismuth. The diet consisted exclusively of equal parts of milk and lime water. He had no doubt that, with the intestinal antiseptics and the cold bath, the entire picture of typhoid had been changed.

DR. SIMON BARUCH remarked, regarding the tendency of the profession to make the bath mild for the patient, that he was convinced it was a mistake. Unless we followed Brandt's method strictly, we could not expect to get his perfect results. Dr. Baruch applied the method in every suspicious case of fever until the diagnosis could be made, and continued it in the cases proven to be typhoid. The temperature of the water was 65° F.; repetition in three hours.

DR. CHARLES E. QUIMBY mentioned a case in which the attending physician was trying to reduce the patient's fever by opening windows. It did not succeed, while tubbing did. He thought the explanation was that cold alone applied in that manner drove the blood from the surface capillaries to the interior, and tended to raise rather than lower the temperature. The tubbing brought the circulation to the surface and acted upon the nervous system. A few years ago leading men in the profession had opposed the Brandt method in this hall, while to-night no voice was raised in opposition. Dr. Baruch had convinced us of the efficacy of the method.

DR. THORNLEY closed.

Kidney Diseases in Relation to Disturbances of the Alimentary Tract.—DR. WILLIAM VISSMAN read the paper. It was customary to divide diseases of the kidneys into three classes—those affecting the epithelial lining of the tubules, those spending their force upon the interstitial tissues, and those affecting both epithelial cells and interstitial tissues. Clinically the diagnosis of the several classes was not unusual, but anatomically one seldom found the line of demarcation between the first two well defined. The blood-vessels of all organs of the body at times revealed the same type of lesions found in the blood-vessels of the kidneys. Post-mortem examination of the bodies of persons who had succumbed to kidney disease usually showed some lesion somewhere in the parenchyma of the alimentary tract. Naturally, the functions of these organs would be interfered with in proportion to the lesion. It was only necessary to refer to any epidemic of Asiatic cholera, in which many apparently healthy persons succumbed to the disease, to prove that they must have had some condition which interfered with the healthy function of the stomach, for the cholera spirillum could not stand the healthy secretions of that organ. Most people committed indiscretions of diet, taking food too hot, too cold, etc. The conse-

quences of such indiscretions were many. It was hardly to be supposed that one would always take sterile food, but it was reasonable to suppose that he would reject food containing pathogenic micro-organisms. The former, however, might not always prove harmless. A nourishing bouillon would be found sour and containing many micro-organisms after standing for a time in a glass. The same changes would take place in the alimentary canal if its physiological function were disturbed. According to the micro-organism would a certain well-defined disease be produced, such as cholera, diphtheria, etc. The constitutional effects on animals into which the germ products were injected varied more or less. In children suffering from summer diarrhœa, we saw symptoms of uræmia in mild degree, even coma and convulsions. Autopsy was likely to show kidney lesion, but generally nothing more than cloudy swelling of the parenchyma. Often cleansing of the bowel so mitigated the symptoms as almost to convince one that they had been due to absorption of something from the alimentary tract. That indican, which appeared in the urine under certain conditions, originated in the alimentary tract, was evident from the fact that it disappeared from the urine when that tract was thoroughly cleansed. It was also probable that some bacteria, including some of the non-pathogenic, entered the circulation and appeared in the kidneys and urine. Further, the product of dead bacteria might produce suppuration. It was only necessary to examine the kidney of a patient who had succumbed to an infectious disease to find proof of some of the facts mentioned. Cloudiness was seen, up to the most serious changes. The object of the paper, however, was to impress the close etiological relation of disturbances or lesions of some form in the alimentary tract to diseases of the kidneys. A great many persons suffered from slight damage of the alimentary canal without even suspecting it. Their urine might be pronounced normal, but careful examination at different times might show it to be highly acid and irritating, or give other evidences of not being normal. Persons supposing their bowels to be acting normally, might on close questioning be found to have two or three small passages a day, while there still were scybalous masses obstructing the bowel and constituting ideal lodging-places for bacteria. Perhaps these facts would account for the large number of cases of kidney lesions among commercial and professional men.

Dr. R. C. M. Page opened the discussion. The profession had not yet entirely freed itself of the false belief in the uræmic theory of the symptoms accompanying kidney disease. The three prominent factors were depreciated condition of the blood, irritability of the nerve centres, increased arterial tension. There were many evidences of certain symptoms being due to gastro-intestinal disturbance. For the convulsions he calmed the nerve centres by hypodermic use of morphine, and relieved arterial tension by the same use of Norwood's tincture of veratrum viride. Between the attacks much was to be gained by attention to the gastro-intestinal tract.

Dr. C. E. Quimby expressed gratification at the fact that Dr. Vissman had come to the same conclusion by pathological study that he had himself arrived at from clinical observation. We had all heard something of New England frugality. The history of one family there had taught him some new facts bearing on the discussion. The parents and all the children except one suffered in various ways from gout, rheumatism, tuberculosis, etc. That one son drifted from home to New York, dropped the frugal ways of his parents, ate plenty and drank some whiskey. He alone was free from headaches and various other symptoms. Malnutrition had something to do with this question. Arteries did not have to be hard to be more or less degenerated.

Dr. Thomas E. Satterthwaite said there was a class of cases in which he believed the intestinal contents actually poisoned the system. He referred to the condition in which there was diminution of pancreatic juice. He believed it had been shown that the pancreatic juice was antiseptic, and if it were absent from the intestine the fæces would be capable of poisoning the system. The fact had apparently been overlooked in text-books that there were many cases of enteritis, especially in children, which were followed by nephritis. Intestinal irrigation was very important.

Dr. H. D. Chapin had repeatedly seen cloudy swelling in the kidneys in fatal cases of enteritis in children.

Dr. Vissman said he had tried to impress the fact that there were a great many slight troubles along the alimentary tract, such as caused the patient apparently no inconvenience, yet which interfered slightly with nutrition. A great many of these people got up a very slight nephritis; they led a comfortable life for many years; the urine might show nothing unless examined at just the right time, perhaps just after considerable exercise, when some albumin would be found. At other times we might find only peptones. But such patients suffered some from malnutrition, and nearly all of them from some arterial degeneration. It was not necessary that the change extend to the point of causing calcareous degeneration. But the walls were thickened and weakened, which was the probable cause of so many cases of apoplexy in comparatively young men.

Report of Committee on Leprosy.—Dr. George B. Fowler, chairman of the committee appointed to report on the contagiousness of leprosy in New York City, and the importance of its segregation here, read the report. It said in part: Judging from experience in the past, whatever prospective danger there may be from this source (leprosy) it is not such as to create alarm, and is certainly not imminent. In regions where the disease is apparently on the increase through the development of new cases, it is a menace to the community and segregation may be justifiable and proper. To adopt the principle of segregation here, and apply it indiscriminately to all lepers, would be unnecessarily arbitrary. It would be on the part of the authorities who should carry it out tantamount to proclaiming the existence of a serious danger to the community when in reality the danger is slight, and by so much create an alarm which is unnecessary, and add to the popular prejudice against the disease and its victims that is already excessive. The indiscriminate enforcement of this treatment would entail great and unnecessary injury upon many lepers. There is reason to believe that under such treatment the disease would run a less favorable course. It lay with the discretion of the city authorities as to what should be done with indigent lepers. As all lepers were liable to become a public charge, it was recommended that they be excluded from our port, as far as possible. The report was signed by Drs. G. H. Fox, H. G. Piffard, E. B. Bronson, A. H. Smith, and the chairman, Dr. Fowler. It was accepted by the society without debate.

Special Committees.—The President appointed the following special committees: On the abuse of public charity, Drs. Chapin, Polk, Ball, Wiggin, Burtenshaw, Cole, Bullard, Hadden, Boldt, Rottenberg, Washburn. Legislative committee, Drs. Van Fleet, Roosa, Grandin, Nammack, Pryor.

Civil Service for Hospital Appointments.—Dr. F. R. Sturgis offered a resolution requesting the legislature to place hospital appointments in New York under civil service rules. It directed the counsel for the society to draft an appropriate bill. Dr. Grandin also spoke to the resolution, and it was adopted without opposition.

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

THE POLLING FIGURES—A TRIAL FOR SLANDER—SIR C. BROWNE'S APPEAL—CURIOUS CASE OF AMNESIA—OPERATION FOR VIOLENT JACTITATIONS—RENAL TENSION AND OPERATIONS—CEREBELLAR TUMOR OPERATED ON—SIR W. MACCORMACK—BELFAST HOSPITAL MOVEMENT—HOSPITAL REFORM.

London, December 19, 1896.

A good deal of surprise is being expressed at the figures of the polling for the General Medical Council which have been officially published. With all the excitement in large places and with unprecedented electioneering tactics, the number actually voting seems to decrease with each election. It is strange that about half the electors should not have taken the trouble to fill up and post their voting papers. Out of 22,577 issued, only 11,990 valid papers were returned, though 237 invalid were sent in, of which 115 were not signed, 15 were quite blank, and the others irregular. These facts are curious enough, but it remains to add that the proportion voting on the three elections that have taken place has regularly declined. Mr. Brudenell Carter, who disapproves of "direct representation," has offered a further contribution in explanation, though with less than his usual taste and acuteness he attempts to belittle the position of the successful candidates and says they have no right to speak in the name of the profession, because a majority of the profession did not vote. If those elected by valid votes of 4,910, 5,369, and 6,646 respectively have not this right, how can Mr. Carter have such right, seeing he is only appointed by the governor and assistants of Apothecaries' Hall, a trading company, of which hardly a dozen members have appointed him? If I admit with him that direct representation, as now established, is a "farce," what is the proper word to apply to his own appointment? The real moral of the election is that the constitution of the council must be altogether changed before the latter can obtain the confidence of the profession.

A trial for slander between two doctors has occupied the law court for eight days and the jury has awarded £75 damages to the plaintiff. This painful case arose thus: The plaintiff attended a gentleman for indigestion and lithæmia. Later on appendicitis developed. The patient's brother, a doctor, came to see him from some distance, and seems to have said that it was no doubt appendicitis from the first and that the case was aggravated by erroneous diagnosis and treatment. The evidence was very contradictory and the jury was left to decide on which side the truth lay. It seems, however, a curious tribunal to which to submit many of the recondite medical questions which were brought forward. The trial will certainly not tend to increase the esteem of the public for the profession or to remove the belief that doctors always differ.

Another legal case is that of Sir Crichton Browne, whose appeal has been successful. You will remember a nurse sued him for refusing to put to a meeting over which he presided a resolution she had sent him. Her resolution was not sent in the manner required by the laws of the association. She was doubtless supported by a discontented set who wanted to get control of the association of nurses of which this was a meeting. The fact is, nurses have been so petted and flattered that many of them think themselves more important than doctors. If things are to go on in this way, we may soon be worse off than before the rise of the modern nurse, who, with all her excellences, does not always seem to "know her place."

A remarkable case of amnesia of eighteen years' duration, with the result of a necropsy, has occupied the attention of the Medico-Chirurgical Society. It was brought forward by Dr. Bastian, who has observed it at intervals since 1878. The voluntary speech was limited to a few words, but the man could repeat words he heard and understand what was said to him. He spent much time in reading and evidently understood what he read, but could not read a single word aloud nor write one from dictation, but could copy it when placed before him. At the post-mortem there was found complete atrophy of the convolutions supplied by the middle cerebral artery, extending inward so as to lay open the lateral ventricle—thus the region was occupied by a pseudo-cyst. The supramarginal and angular gyri had also disappeared, as had the posterior two-thirds of the upper temporal convolution. Dr. Bastian suggested that the atrophy of the convolutions occurred at an unknown period of the illness and that functional compensation must have gradually taken place from development of the corresponding opposite centres. Sir William Broadbent did not quite agree with this, and called to his aid two extra centres, viz., an idea centre and a propositionizing centre. Of course it is easy to imagine any number of centres, but until some evidence of their existence is offered beyond a suggestion to explain a single case the majority will be content to confess ignorance. The discussion of the case was adjourned, and at the last meeting Mr. Spencer Watson resumed it and remarked that number symbols differed from word symbols, as they were learned by rote, were related to touch, but never associated with emotion. The president, Dr. Dickenson, related a case in which there was remarkable separation of aphasia and agraphia, suggesting that the subject wrote with one side of the brain and spoke with the other. He was a left-handed man. The speaker alluded to the case of Dr. Johnson, who, it will be remembered, lost the use of speech but wrote as usual—in fact wrote Latin verse and a Latin letter to Dr. Heberden, and thus satisfied himself that he retained his intelligence. Dr. Bastian replied, after which Dr. Guthria described a case of violent jactitations of twenty-two years' duration, affecting chiefly the left arm and leg, but involving in a less degree the opposite limbs. At last trephining was done and the right motor area of the cortex removed. Paralysis of the left hand and arm followed, but lasted only a week, during which seventeen epileptic fits occurred. Symptoms of partial bulbar paralysis also occurred for several days. Normal action of the arm gradually returned, but jactitations soon supervened, and three months after the operation the case was just as it had been before. It was admitted that in severe cases, such as this, the possible advantages of operation are overbalanced by the dangers.

At the last meeting of the Clinical Society Dr. David Newman, of Glasgow, had an interesting paper on "Increased Vascular Tension in the Kidney as a Cause of Renal Pain, Hæmaturia, and Albuminuria." The causes of increased tension are, as he said, mechanical in some cases and in others morbid processes. He related four cases due to direct mechanical interference and three due to morbid conditions. The latter illustrated the benefit to the patient of relieving the tension even when, as in some of the cases, there did not appear on operation the condition anticipated. In the discussion on this paper, several cases were cited in which the kidney was cut down upon and even incised in search of a stone which did not exist, and yet the patients were greatly relieved. In one the speaker said his patient passed such a large amount of uric acid after the operation that the urine was almost solid

on cooling. It was suggested that in these cases manipulations of the kidney might dislodge uric acid which blocked the tubules. At any rate, it is well known that patients have lost their suffering after these operations. The president, Dr. Buzzard, grimly congratulated surgeons, as they seemed to relieve patients even when they operated on mistaken diagnosis.

The president made another *bon mot* in the evening, in commending another surgeon for waiting a year and a half before bringing forward his case, as surgical cases improved by keeping, like wine. This case was one of cerebellar tumor removed by Mr. Parkin, of Hull, from a child of four years. A portion of each lateral lobe and the posterior part of the middle lobe were excised. The tumor was of a gliomatous nature. Up to date there has been no return of the symptoms. The child has had whooping-cough and measles since the operation, but now remains quite well.

A case of excision of the cæcum for colloid cancer also occupied the attention of the meeting.

Sir W. MacCormack may be considered convalescent, as he has been out for drives.

Belfast is going in for a new hospital to celebrate the Queen's long reign. The lord mayor has contributed largely and the wealthy citizens are following the example. Lord Dufferin at a meeting on the 9th inst. made an excellent speech on the use of hospitals.

Mr. Garrett Horder, founder of the Hospital Reform Association, delivered a most interesting address recently at Manchester, in which he traced the history of the movement in favor of the reform he is so powerfully advocating.

OUR PARIS LETTER.

(From our Special Correspondent.)

DEATH OF PROFESSOR STRAUS—LEAGUE AGAINST ALCOHOLISM—SUBSTITUTION OF FEMALE FOR MALE EMPLOYEES IN GOVERNMENTAL DEPARTMENTS—CONGRESS TO PROTECT AND INCREASE THE POPULATION OF FRANCE—DANGER OF DEPOPULATION—THREE NEW HOSPITALS FOR CHILDREN—PROFESSOR BOUCHARD'S NEW APPLICATION OF X-RAYS—THE "CHEMICAL DISEASE"—DR. ROUX'S DECORATION—PROFESSOR DIEULAFOY AT THE HÔTEL DIEU—HIS BOOK, ETC.

PARIS, December 28, 1896.

THE Faculty of Medicine and corps médical of the Parisian hospitals have just met with another loss in the person of Professor Straus. We had hardly recovered from the shock caused by the sudden demise of Professor Hanot, when Straus fell almost as suddenly. Professor Straus' more intimate friends had known for some time past that he was a martyr to angina pectoris and it was an attack of that dreaded disease that caused his death. His colleagues, students, and friends were devoted to him. He was one of the most esteemed professors at the Faculty of Medicine and his course of lectures on bacteriology always one of the most crowded. His works on charbon (carbuncle or pustule maligne), tuberculosis, and cholera need no encomium; their author was a patient, careful worker, and his contributions to science were of the highest order.

A national league against alcoholism has now been formed, and it is to be hoped that the effect of the league upon this ever-increasing evil will be practical as well as moral. On Sunday a meeting of the league took place in the grand amphitheatre of the "ecole pratique" of the Faculty of Medicine, presided over by Professor Brouardel, dean of the faculty. Professor Laborde proved by experiments the toxic effects of alcohol and the essences used in the preparation of apéritifs (or drinks before dinner having an aperient action the following morning) and absinthe. He was followed by Dr. Legrain, who pointed out the deleterious effects of alcoholism on the individual and his descendants, demonstrating by tables the frightful progression of the consumption of alcohol and the baneful consequences resulting therefrom. Dr. Philbert, after thanking on behalf of the league the president and speakers, closed the meeting by an appeal to the public to give their support to this great and good work.

The substitution of female for male employees has been made in several of the governmental administrations, for instance, in the postal and telegraphic departments, and one point that touches medicine directly is to know which of the two sexes is most subject to lighter ailments and in consequence to absence from service. It would seem that the women have largely the disadvantage of the men in this respect. The following figures are taken for one year and show that the average of absences for cause of the milder forms of disease have been 19.2 days for the men and 33.5 days for the women; in other words, 17.4 days of indisposition for the women against 100 for the men. This is a much higher average, as far as the women are concerned, than in either Switzerland or Great Britain, the average in the latter country being 154 for the women and 100 for the men.

The second congress to protect and increase the French population is now in progress and will continue its daily sittings until December 20th inclusive, under the auspices of many notabilities and the French branch of the Alliance of Learned Men and Philanthropists, the presidents of honor being the ministers of the interior and of public instruction. The object of the congress is to enlighten the French people upon the gravity of the situation and to stimulate them to put into practice propositions capable of immediate application, the Alliance of Learned Men and Philanthropists considering it an imperious duty to raise a cry of alarm and to tell patriots the whole truth in order that they may take steps to prevent France from perishing and may hold the country in respect before its enemies. Blinded by past glories and present prosperity, considering France the first country in the world, they lose sight of the fact that in Europe France is the country where the fewest children are born and where the most die, and if that continues the result will be that the neighboring nations, which increase more and more, will surround France like so many wild beasts ready to devour her.

The society or alliance seems to think the danger can be averted, or at least attenuated, and hence the congress has been called in order to act in the matter before it is too late.

The following are some of the subjects that will be discussed: "Extension or Increase of Nuptiality and Natality," by M. Levasseur of the Institut: "Increase of Natality," under the presidency of Dr. Dumontpallier of the Academy of Medicine;" "Protection of Maternity," by M. Alfred de Foville, of the Institut: "Protection of Children in the First Years of Life," by Dr. Théophile Roussel, of the Institut, senator: "Protection of Children of All Ages," "Protection of Adults," etc.

At the final sitting on Sunday, December 20th, Dr. Charles Richet, the eminent professor of physiology, will endeavor to devise the means of adopting the views of the congress and of putting them into practical working.

Absinthe drinking, cigarette smoking, abortion, preventing conception, prostitution, and mistress keeping are evils too firmly rooted in France to be swept away by any set of resolutions or by the action of any congress or leagues—to say nothing of the fact that, as

things exist to-day, young men are actually discouraged from matrimony. Dr. Bertillon's remedy is to tax households without children. The object is certainly praiseworthy, but the task, alas! that of sweeping out the Augean stables.

The increase in the number of sick and weakly children has warranted the transformation in the near future of the Hérold Hospital into a children's hospital. In addition to this transformation two other hospitals will be constructed, one in the Rue Michel-Bizot, the other in the Rue Etex, both for children.

These facts add strong confirmation to the assertions made in the congress, and are exactly what might be expected as a result of existing causes already referred to.

An extremely interesting clinical application has been made by Professor Bouchard with the famous Roentgen rays. He has shown us a series of radiographic proofs that in their way surpass anything that has as yet been done with the rays, at least in so far as the practice of medicine is concerned. The proofs of the first series give perfectly delineated images of a pleuritic effusion at the different stages of its resorption. In one of them, in which the pleurisy is complicated with an intercurrent complication, the induration at the summit of the lung is distinctly and clearly marked.

The proofs of the second series have reference to tuberculosis, giving the photographs of the thoracic cages of a number of patients affected with pulmonary tuberculosis. The presence of two caverns diagnosed by auscultation and percussion is confirmed in a most remarkable manner, as are also other lesions.

Enough has been said in this brief note of Professor Bouchard's valuable and new contribution to science, to show from a clinical standpoint what immense services the *x*-rays are destined to render in confirming the diagnosis made by auscultation and percussion, not only in cases of pleurisy but also in pulmonary tuberculosis and pneumonia, more especially in the stage of hepatization.

We may look for still further interesting results shortly in this field, as Professor Bouchard assures us that he intends to prosecute his studies with the radiograph in other diseases as well.

The "chemical disease" is a new name given to an old malady that is just now raging in France, in a form bordering on the epidemic; endemic it most assuredly is, and that to an alarming degree. We refer to phosphoric necrosis, which is playing havoc with the workmen engaged in the manufacture of matches, to such an extent that the government has called the Academy of Medicine to the rescue.

It is curious, however, that it is only in France that the disease is so flagrant, so tenacious, and so deep-seated; for instance, of two hundred and thirty workmen recently examined by Drs. Vallin, Magitot, and Monod in the great manufactories of matches at Aubervilliers and Pantin, in the environs of Paris, only seventy could be passed as absolutely valid; one hundred presented symptoms of more or less gravity. All of them required careful and specific treatment. In addition to this, thirty more were put on the invalid list.

It is the white phosphorus that is so highly toxic, and the problem to solve is how to exclude this dangerous component from the fabrication of matches and produce a match in other respects equal to those with, say, permanganate or chlorate of potassium as a basis.

It will be remembered that by a decision of the Academy of Medicine the antitoxin prize of 25,000 francs, known as the "Saint Paul prize," was to be evenly divided between Dr. Behring, of Berlin, and Dr. Roux, of Paris, the present director of the Institut Pasteur. In accordance therewith, on the 15th of December the prize was officially awarded, and on that very day arrived a dispatch from His Majesty the Emperor William of Germany, conferring upon Dr. Roux the Order of the Crown. *Noblesse oblige.*

Dr. Dieulafoy, the distinguished professor of internal pathology, was not long ago transferred from the Necker Hospital to the Hôtel Dieu. A clinical professorship at the Faculty of Medicine of Paris with a service in the Hôtel Dieu is considered the highest and most coveted medical or surgical position. Professor Dieulafoy's manual of internal pathology is just beginning its sixth edition. Revised and enlarged, it has grown from two volumes to three, with fifty-nine drawings and seven colored plates. It is now a veritable treatise of medicine, being at the same time a marvel of precision, exactness, and exposition, in accordance with the advanced science of the present day. The book has always been as popular with doctors and students as the author himself. Dieulafoy is a universal favorite, whether in the lecture room, at the hospital, or in private practice.

WHAT MOSES KNEW ABOUT LEPROSY.

To the Editor of the Medical Record.

Sir: Just now, when considerable is being said regarding lepers and leprosy, I would like to call your attention to the manner of diagnosis—that is, the way that the Lord told Moses to inform the priests so that they might be able to make a proper one:

When the hair in the plague is turned white, and the plague in sight is deeper than the skin of his flesh, it is a plague of the leprosy.

If the bright spot be white and not deep in the skin, nor the hair turned white, why then the priest is to shut him up seven days. At the end of that time he is to look him over again, and if the spot be somewhat dark and spread not, the priest shall call him clean. It is but a scab, and he shall wash his clothes and be clean. If the priest see that the scab spreadeth in the skin, then he shall pronounce him unclean, for it is the leprosy (Lev. xiii.).

Chapter xiv. 40–45 says the Lord spake unto Moses about the cleansing of leper houses, and commanded the priests to take away the stones, to scrape the house within, and pour out outside the city into an unclean place the dust that they scraped off, to put in new stones and mortar, and plaster the house again. If the plague broke out after all this had been done, he was to break down the house, the stones and the timbers and the mortar, and cart them all away out of the city.

Some first-rate authorities do not consider this a contagious disease, but the above vigorous measures show pretty clearly how Moses viewed it thirty-five hundred years ago, and he had good authority to back up his statements.

Do any of your subscribers ever read the Bible? If so, they will find very interesting reading round about Leviticus xiii., xiv., xv.

CATAPHORESIS IN TUBERCULOSIS.

To the Editor of the Medical Record.

Sir: I noticed in a recent number of the Medical Record that a committee had been appointed by the Paris Academy of Science to investigate an alleged cure for consumption practised by Dr. Crotte. The item briefly states that: "The method comprises the use of electricity and antiseptics, the electricity being employed to open the way for the parasiticide."

This may or may not be the same idea which I have been working upon in a small way since last June. I

use the continuous galvanic current, and medicate the positive electrode. Having made the diagnosis and located the diseased area, I place one electrode upon the front and another upon the back of the chest, with the affected portion of lung between them, using electrodes of at least six inches in diameter. Pieces of wire gauze well padded with absorbent cotton make good electrodes for the purpose. Upon the moistened cotton of the positive electrode I sprinkle a solution of iodine and iodide of potassium, and use a current of about twenty milliampères for fifteen minutes. I find that quantity is about all the patient will bear, on account of the pain which comes with a stronger current. The treatments have been repeated every second day at first, and at longer intervals later.

I have used the treatment in six undoubted cases of consumption, and though the time has been too short to make any positive deductions, I must say I am greatly impressed with the results obtained. Two express themselves as cured, and appear to be. The others are much improved, with the exception of one little patient, who was so frightened that the parents desisted from the treatment. Whether the results are due to cataphoresis, the iodine reaching the diseased tissue and acting as an antiseptic, or to the antiseptic effect of the continuous current, or to both, I do not pretend to say. Further experiment would determine that point.

LINEAR ELECTROLYSIS FOR STRICTURE.

To the Editor of the Medical Record.

Sir: In your issue No. 20, of November 14th last, you published an article by Dr. Ramon Guitéras, of New York. In speaking of operating for stricture by means of my linear electrolyzer, Dr. Guitéras makes a few errors which I beg to correct, in order that your readers may thoroughly understand the operation in question. Dr. Guitéras states that:

1st. I have only recently invented the electrolyzer.

2d. That it resembles the Maisonneuve urethrotome.

3d. That the operation lasts from thirty seconds to four minutes.

4th. That after the operation the urethra will admit an 18 F. sound.

5th. That the stricture can be still further enlarged with the Otis urethrotome.

Permit me in a few words to show that the writer has not fully understood my method.

1st. I invented and have been using the electrolyzer for the last fifteen years, or in other words since 1881.

2d. The electrolyzer does not resemble the Maisonneuve urethrotome, the latter being composed of three separate pieces which adjust themselves during the operation; the former is composed of one single piece, and resembles a small whip from which, toward the centre, a platinum blade projects. The practical value of the instrument is at once apparent in the fact that it is composed of but one piece. The metal end acts as a conductor for the electric current which is applied to the platinum lance, and, as the latter is placed in contact with the stricture, there is no posibility of error or laceration.

3d. The operation, as a rule, lasts from twenty to thirty seconds. It should not last longer than a minute, and if it does the current should be stopped and a urethrotome used. An operation which lasts four minutes is worthless. In 1893 in a paper which I had the honor of addressing to the Academy of Medicine of Paris, I demonstrated from operations performed that there were five or six soft strictures for every hard one.

4th. In place of passing an 18 F. sound after the operation, as a rule 22, 23, or 24 F. can be used.

5th. In regard to making further enlargement afterward by means of the Otis urethrotome, such a statement is directly contrary to the principles taught by me in the use of the electrolyzer.

My sole idea in perfecting the electrolzyer was to avoid bloody operations and the use of urethrotomes, on account of their danger, from which my method is entirely free.

If under such circumstances the Otis urethrotome is used, it places the patient, who has already undergone one harmless operation and then a second dangerous one, in a state of danger. Such action would stamp my method as inferior, in fact, as preliminary to the use of the Otis urethrotome.

I must protest against such a statement, which is entirely incorrect. My electrolyzer cures equally well and better than urethrotomes, and is amply sufficient in itself.

Dr. T. A. Fort.
31 Rue François Premier, Paris.

CATARRHAL SALPINGITIS.

To the Editor of the Medical Record.

Sir: In your issue for December 19th, Dr. Adelaide Lambert makes some strictures upon Case III. reported in my article on "Catarrhal Salpingitis" in the Medical Record for November 21st. She states that she fails "to see that he proves Case III. to be one of catarrhal salpingitis." There is nothing surprising in this failure, but what is surprising, nay, even inexplicable, is that she also fails to see that the case was not reported as one of catarrhal salpingitis at all, but as an instance of general peritonitis from an obscure cause which was mistaken for acute appendicitis. To quote from my article: "The next case (Case III.), though strictly not belonging to the disease (catarrhal salpingitis) under consideration, affords another striking example of how a general peritonitis, in some obscure way depending upon the generative organs, can be mistaken for an acute appendicitis." The case was reported in illustration of the difficulties frequently encountered in the diagnosis of abdominal affections, and to serve the purpose of teaching a lesson which often can be more forcibly done by our errors than by our successes.

To those who know medicine from observation at the bedside, the error, which was also shared by two eminent consultants, will appear excusable; to the others I make no explanation, as they would fail to understand it. The several questions the doctor asks show further that she read the article very carelessly and superficially. "What benefit did she receive from the operation?" The benefit that accrues from treatment that aims to be based on knowledge and not on blind chance by giving medicines haphazard. A careful reading of the history of the case will convince one that the symptoms justified an exploratory incision. I can safely assert this was attended by fewer dangers and ill effects than the administration of a powerful purgative would have been. To another question put, I can only answer that she did receive "the same treatment before the operation as she did when her life was despaired of."

The premature birth of the child had nothing whatever to do with the operation, for in the first place the child was not born spontaneously. When the abdominal distention grew more and more intense and threatened life by interfering with breathing, labor was induced, and finally manual dilatation was done and the child extracted, as is clearly recorded in the paper. Under the circumstance I should have been only too glad had the exploratory laparotomy been followed by spontaneous expulsion of the child. From a close observation of the case at the bedside, and from sub-

sequent thought and study, the conviction has been gained that the peritonitis and partial obstruction of the bowels were due to the gravid uterus pressing against the sigmoid flexure, producing an incomplete occlusion of its lumen. Had the uterus not been emptied when it was, the vomiting would soon have become stercoraceous (it already had a suspicious odor) and the end would not have been far off. The critical condition following the emptying of the uterus was, no doubt, due in part to the shock attending the procedure and in part to the preceding peritonitis, which did not immediately subside on the removal of the cause.

The doctor saw nothing alarming in her condition as reported. I admire and envy the doctor's temerity. As for myself I must confess to a certain degree of timidity, and when a patient, pregnant or not pregnant, presents the symptoms of general peritonitis and has a temperature of 104.8° F., a pulse varying from 170 to 180, I must own to a feeling of considerable anxiety.

From what has gone before, it will readily be seen that I entirely agree with my critic when she says "the case was just as good an illustration of the mania for operating as of catarrhal salpingitis."

Now for a few general remarks to my critic and to future ones of that ilk. Before assuming the rôle of censor and mentor, the critic ought in justice to the author and the readers of the MEDICAL RECORD peruse the article carefully and with a modicum of discernment. Had the critic in this instance followed this very obvious course, the author would have been saved some trouble and the readers of the MEDICAL RECORD some confusion of thought and waste of time. My critic, like many others, has caught upon a phrase, "the mania for operating," and flings it at random in place and out of place, as chance may have it.

The whole tenor of the article which she criticises is strongly against indiscriminate operating, and in the three cases reported in full only one patient was subjected to operative interference, and that only after due thought and consultation with as able counsel as this city affords.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending January 2, 1897:

	Cases.	Deaths.
Tuberculosis	201	100
Typhoid fever	19	7
Scarlet fever	127	8
Cerebro-spinal meningitis	2	2
Measles	132	5
Diphtheria	240	35
Laryngeal diphtheria (croup)	15	4
Chicken-pox	18	0

Hard Lines for an American Doctor.—A singular verdict was returned by a jury at the London sheriff's court last week in a libel action, remitted from the high court. The plaintiff, Mr. Ferdinand, is an American doctor, practising in Chelsea. The defendant, Mr. Richard Brown, is a medical man in Peckham. These gentlemen apparently are rivals and have on various occasions addressed audiences on medical—and personal—matters in public places. It seems that the defendant in some of his public utterances characterized the plaintiff as a fraud and a liar, and stated that he had killed a woman by his treatment in three weeks. For this serious libel the plaintiff claimed £2,000 damages. Judgment went against the defendant by default in the high court, and it became the task of a jury in the sheriff's court to fix the damages. The jury awarded the plaintiff just 5*s*. It would be interesting to know the mental process by which this result was reached. Of course, it has to be kept in view that the jurors see the witnesses and hear their evidence, and so are in a favorable position for estimating the rights and wrongs of a case. But, after every allowance on this score has been made, the verdict still bears an ugly resemblance to a miscarriage of justice.—*The London Standard.*

Hysterical Polyuria.—Most instances of simple polyuria or of diabetes insipidus belong to the class of hysterical polyurias. The term diabetes insipidus is destined to disappear from medical nosology. Hysterical polyuria exists either alone or associated with stigmata of hysteria, or with psychical or physical stigmata of degeneration. Chloruria would seem to be a constant sign of this form of polyuria. Suggestion holds the first place in diagnostic and therapeutic importance, but valerian and hydrotherapy also influence this condition.—KOURILSKY, *Thèse de Paris*, 1896, No. 383.

Books Received.

While the MEDICAL RECORD *is pleased to receive all new publications which may be sent to it, and an acknowledgment will be promptly made of their receipt under this heading, it must be with the distinct understanding that its necessities are such that it cannot be considered under obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

RESECTION OF ARTERIES AND VEINS INJURED IN CONTINUITY—END-TO-END SUTURE—EXPERIMENTAL AND CLINICAL RESEARCH.

BY J. B. MURPHY, M.D.,

CHICAGO.

THE idea of suturing an artery after it had been injured was conceived by Lembert, and a case is reported by Broca in 1762 in which suture of a longitudinal incision of an artery was successfully made. Assmann in 1773 treated of it in a dissertation at Gröningen. The latter made two experiments on animals; both resulted unfavorably through an obliterating endarteritis. He then abandoned the work. Henry Lee, of London, in 1865 made some experiments with puncture to ascertain how large an opening could be made without fatal hemorrhage, and described the method of repair in arteries without suture; Beale made an extensive microscopic examination of Lee's specimens, giving the pathologic histology of repair.[1] In 1883 Gluck reported nineteen experiments with arterial suture, but in all of these cases his efforts were futile, because he was unable to control the hemorrhage from the needle punctures through which the suture was introduced. He also devised aluminium and ivory clamps for the purpose of uniting longitudinal incisions in the vessel, and succeeded with the ivory clamp in one experiment on the femoral of a large dog.[2] Von Horoch, of Vienna, had thrombosis in six experiments, including one end-to-end union (1887). The most extensive and indeed the only work of true merit performed in this line was by Dr. Alexander Jassinowsky, of Odessa. His first paper was read in Dorpat in 1889; his second was published in *Langenbeck's Archiv*, 1891. Bruci in 1889 sutured six longitudinal incisions in arteries of dogs, and was successful in four. Tansini, of Modena, in 1890 endeavored to close the arteries by absorbable horn clamps. Muscatello successfully sutured a one-third division of the abdominal aorta in a dog. Heidenhain, May 28, 1894, closed by catgut suture an opening in the axillary artery one centimetre long, which was accidentally made while removing adherent carcinomatous glands. The patient made a good recovery; circulation in the extremity was not disturbed. In the same year, 1894, Robert Abbe made some very interesting and instructive experiments, placing sterilized glass tubes in vessels with the intention of uniting them and re-establishing the circulation.[3] Von Zoege-Manteuffel in April, 1895, operated on an arterio-venous aneurism in Scarpa's triangle. He wounded the common femoral and made a successful lateral suture of the wall.[4] J. Israel, in discussing Gluck's paper, mentioned that he had closed the common iliac, which had been torn for two-thirds of its circumference in an operation for a perityphlitic abscess, by inserting five fine silk sutures through the entire wall of the vessel.[1] It does not seem possible from my observations experimentally, that two-thirds of the circumference of a vessel of the size of the common iliac could be closed with five sutures and have the seam blood proof. Heidenhain endeavored to accomplish the closure of arterial wounds in the carotid of dogs by suture but failed. Sabanyeff, of Odessa, successfully closed a small opening in the femoral artery with suture, in 1896. Billroth, Schede, Braun, of Koenigsberg, Schmidt, and others successfully sutured wounds in veins, and the closure of wounds in veins by suture is now an accepted surgical procedure. I recently closed an opening three-eighths of an inch long in the common jugular with five continuous silk stitches. Small openings in veins have frequently been closed with lateral ligature. I cannot find recorded a case in which an artery has been sutured after complete division.

For the purpose of determining whether this were practicable, and whether a considerable portion of the artery could be resected, I have performed the following experiments:

EXPERIMENT No. 1.—March 4, 1896; male dog, weight forty pounds. An oblique incision dividing one-third of the circumference of the left common carotid was made and closed with a continuous silk suture penetrating all the coats of the artery: only a small portion of the artery was denuded. There was some hemorrhage from needle punctures after the clamps were removed, which subsided rapidly under digital pressure; the wound was closed. The dog showed no unpleasant symptoms after the operation. There was a slight swelling on the left side, which lasted about a week.

Post-mortem, March 25th, twenty-one days after operation: There was some new-formed connective tissue at the seat of operation. The sutures were not infected; the calibre of the vessel was only slightly diminished. The silk was covered and could be seen under a thin layer of exudate from the inner side of the vessel. There was no thrombosis. The intima had been fractured by one of the clamps, at which point it was rough and somewhat thickened.

EXPERIMENT No. 2.—March 4, 1896: dog, weight fifty pounds. The right common carotid was exposed and opened by a longitudinal incision of one-third of an inch. The opening was closed by interrupted sutures involving all the coats. There was some hemorrhage after the clamps were removed, which ceased after a digital pressure of two minutes' duration. The external wound was closed with silkworm gut.

Post-mortem was made March 25th, twenty-one days after operation. There was considerable exudate around the position of sutures, but the sutures were not infected. The wall of the vessel was thickened on the side of the suture. The calibre of the vessel was diminished one-third; the suture was not exposed in the vessel; it was covered with a deposit. There was no thrombus. There was some roughening of the intima at the position where the clamps had been placed.

EXPERIMENT No. 3.—March 7, 1896: hunting-dog, weight about fifty pounds. The left femoral was ex-

[1] The Transactions of the Medico-Chirurgical Society, vol. L., p. 477.

[4] Berliner klin. Woch., No. 34, 1895.

[1] Berliner Cent. für Chir., December 7, 1895.

posed and an incision one-half inch long was made in its wall; it was closed with a continuous silk suture; vessel one-eighth inch in diameter. The vessel was clamped with eight-inch Billroth forceps covered with rubber, care being taken not to compress the artery sufficiently to injure the intima. There was no difficulty in producing an accurate approximation of the margins of the wound with silk suture. A very slight hemorrhage took place through the needle holes after

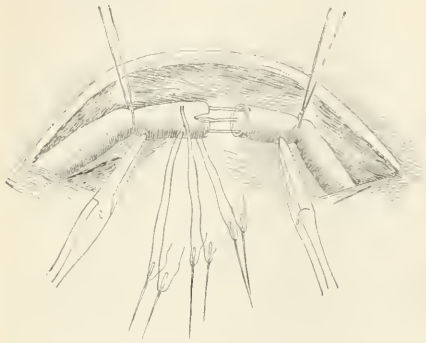

Fig. 1.—Shows Method of Inserting Sutures to Produce Invagination.

the clamps were removed, which ceased in less than a minute. The external wound was closed with silkworm gut.

Examination of left femoral, March 15th, eight days after operation: Union, no hemorrhage, no suppuration; the vessel was completely thrombosed.

Experiment No. 4.—Same day, same dog. Invagination of right femoral after complete division. Two double needled silk sutures were used to draw the intussusceptum one-third of an inch into the intussuscipiens, as shown in Fig. 1. Several interrupted sutures bind the end of the intussuscipiens to the circumference of the intussusceptum (Fig. 2).

Examination, March 15th, eight days after operation: There had been no hemorrhage from the vessel. A slight infection had taken place around the seat of operation. The artery was thrombosed.

Microscopic examination showed the lumen filled with a red thrombus and the wall to consist of two distinct muscular layers, both diffusely infiltrated with round cells. The lumen was very small and the wall very thick.

Experiment No. 5.—March 11, 1896; dog, weight sixty pounds. Large head and neck. Resection of three-fourths of an inch of right common carotid. The proximal end was invaginated with three silk sutures; several sutures penetrating the adventitia and media were used to secure the end of the intussuscipiens to the periphery of the intussusceptum. The sheath was sewed over the vessel. The adventitia was separated from the media on either end. The Billroth clamp forceps were used to suppress the hemorrhage.

Post-mortem, April 15th, thirty-five days after operation: Some periarteritis and adhesions existed. The sutures in the skin had suppurated. The area around the vessel was not infected; there was but little contraction at the position of approximation.

Microscopic examination: There was some thickening in the wall. The thickening in the media was more pronounced than in the intima; the process was not progressive. There was nothing to indicate that the artery would not have remained patulous. The wall of the artery showed no evidence of injury by the clamps.

Experiment No. 6.—March 11, 1896; left common carotid in same dog as in Experiment No. 5. Resection of one-half inch of artery. End-to-end suture without invagination. The suture penetrated all the coats; it was continuous and contracted the artery considerably at the line of approximation. It was made with two needles on one thread and a continuous figure-of-eight stitch. There was a little hemorrhage from the needle holes after the sutures were placed. This subsided under a sponge pressure of two minutes' duration. The sheath was not sutured around the vessel. Clamps were the same as used in Experiment No. 5.

Post-mortem, April 15th, thirty-five days after operation. The wound was suppurating down to the artery. A pocket of pus existed deep in the neck. All of the arterial sutures were exposed in the bottom of the wound. The artery was thrombosed.

Microscopic examination: The artery presented just the opposite condition from its fellow on the left side, described above. The intima was very much thickened and was rapidly obliterating the tube. The histology was that of organization of clot; connective tissue cells and blood-vessels were taking the place of coagulated blood. The media was likewise somewhat inflamed. There was some inflammation along the lymphatics and adventitia, and there were numerous foci of infection. The case was a typical infective endarteritis with formation of coagulum.

Experiment No. 7.—March 15, 1896; dog, weight forty pounds. Longitudinal incision in the right iliac, five-eighths of an inch in length, was closed with a continuous silk suture including all of the coats of the artery. Five days after the operation a very marked swelling appeared at the position of suture and blood began to ooze from the line of union. The dog was again anæsthetized, the cutaneous sutures were removed, the margins of the wound were separated. A clot about the size of a hen's egg was carefully elevated, decomposed. There was an absence of union of the wall of the vessel, and when the clot was removed profuse hemorrhage ensued. A ligature was placed above and below the incision in the artery and that portion of the vessel excised. The cause of the non-union of the vessel in this case, I believe, was infection. There was no clot in the artery.

Experiment No. 8.—March 18, 1896; dog, weight

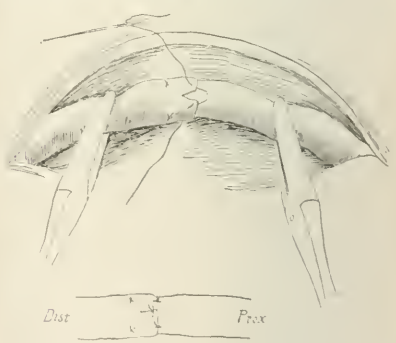

Fig. 2.—Shows Method of Inserting External Sutures.

thirty pounds. A longitudinal incision one-half inch long was made in the abdominal aorta, which was closed with a continuous silk suture including all the arterial coats. A slight hemorrhage occurred through needle punctures after the clamps were removed, which ceased on one and one-half minutes' digital pressure. No effort was made to cover the line of suture with adventitia or peritoneum.

The dog died March 28th. Post-mortem: Retro-

peritoneal abscess around artery. Complete occlusion of calibre of artery. General suppurative peritonitis was the cause of death.

Experiment No. 9.—March 26, 1896; dog, weight sixty pounds. Invagination of left carotid by three double-needled threads attached to the intussusceptum and interrupted silk suture of the intussuscipiens involving only the tunica adventitia and media of the proximal side.

Post-mortem, April 25, 1896: Left common carotid surrounded by considerable exudate and suppuration around one of the cutaneous stitches. A small sinus led down to one of the sutures at the position of approximation. The vessel wall was considerably thickened at the line of union, as shown in Fig. 3. The vessel admitted a considerable stream of water through it immediately after its removal. It was somewhat dilated on the proximal side. The collateral branches were enlarged.

Microscopic examination: Most evidence of endarteritis at 3 and 4 (Fig. 3). Much of the tissue between 2 and 5 seemed accidental. The invaginated walls could be outlined, but the line of demarcation between them was scarcely discernible. The connective tissue around the artery showed a large number of blood-vessels and a cross section of a nerve of considerable size. There was a small amount of inflammation of the vascular and lymph channels at that point. In the adventitia there was a violent acute inflammatory process, with foci which resembled those of suppuration. The showing in the media was the same as in the right carotid. In the intima the process was still more violent. The inner elastic lamina was so broken up as to be unrecognizable.

Experiment No. 10.—Same dog as in Experiment No. 9, same day. Resection of one-half inch of right carotid. Adventitia peeled back. Three double-needled sutures were attached to the intussusceptum and put through the intussuscipiens from within outward, invaginating the intussusceptum one-third inch; then sutured the intussuscipiens to the periphery of the intussusceptum, as shown in Fig. 2. The sheath of the artery was sewed around it; the adventitia was not sutured.

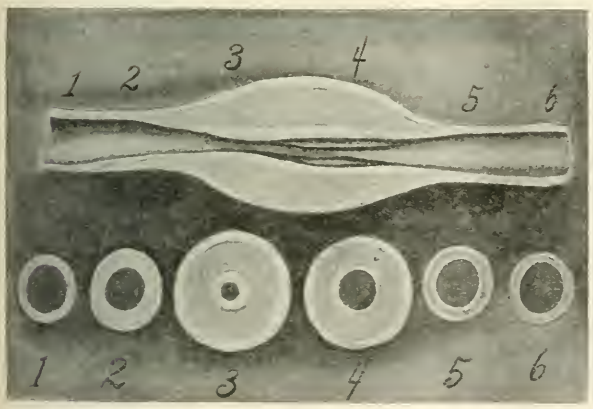

Fig. 3.—Shows the Diminution of Lumen of the Vessel with Thickening of the Wall, form Experiment No. 9.

Post-mortem on right carotid, April 25th, showed no suppuration around the artery; considerable inflammatory exudate; artery enlarged at position of invagination, as shown in Fig. 4. Nerve and vein involved in exudate. Vessel admitted a stream of water about one-half its normal diameter. It was enlarged on the proximal side of the union.

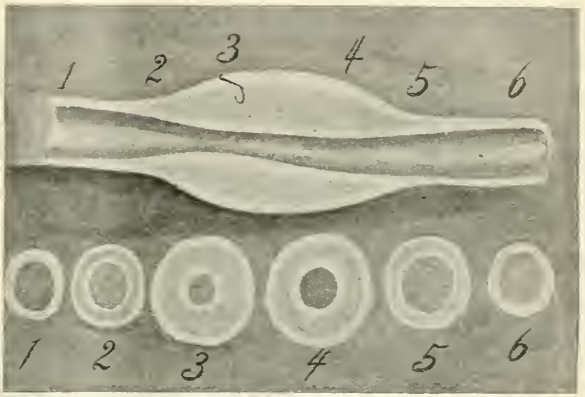

Fig. 4.—Shows the Thickening of the Arterial Wall and Diminution of the Lumen of the Vessel, from Experiment No. 10.

Microscopic examination showed marked evidence of endarteritis. The line just below 3, Fig. 4 indicates suture. At 2 much exudate, but less than at 3. At 4 the lumen is about one-half as large as it is at 1 and 5. The lumen at 3 is one-half of what it is at 5. Most of the tissue between 2 and 5 is foreign. There are a moderate amount of inflammation in the adventitia and a large number of new blood-vessels. Muscle fibres of the media alternate with bands of small round cells. Capillaries in the outer walls are apparent. The region of the intima is the seat of a very marked round-celled infiltration; capillaries can be seen in this coat. The thickness of the intima is markedly increased and the lumen is about one-third of the normal size. There are no endothelia lining the intima. Another section presents the same appearance, except what remains of the lumen is a triangular opening. There are sections of nerves in the loose tissue surrounding the vessel.

It will be noticed that notwithstanding the invagination had been made thirty days previous to the post-mortem there was no clot in the vessel, and the diameter of the lumen was one-third of that above and below the point of union, showing that the endarteritis had progressed slowly.

Experiment No. 11.—April 26, 1896: calf, six weeks old. Excision of one-third inch of left common carotid. Invagination of all coats of proximal into distal end for three-eighths of an inch. The artery was clamped with Billroth forceps. It was found to be elastic and free from tension when replaced. Peripheral sutures were used to secure the invaginated portion, as described above. There was little hemorrhage after the operation was completed. The sheath was sewed around the artery. There was a tumor around the area of approximation with considerable swelling for three weeks after the operation, which disappeared almost entirely before the specimen was removed for examination.

Specimen secured June 1st, thirty-four days after

operation: one and one-half inches of carotid at point of suture was removed and the ends were ligated. There was considerable inflammatory deposit over the entire field of operation. The union of skin was complete. The collateral vessels around the position of approximation were considerably enlarged. The vessel was

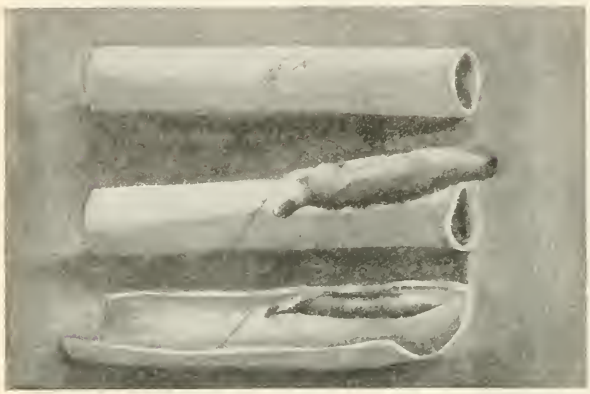

Fig. 5.—Shows the Line of Suture and the Formation of Internal and External Coagulum in Experiment No. 14

not patulous, the lumen being filled by a clot for a considerable space on the distal side of approximation; it extended but one-fourth of an inch on the proximal side.

Microscopic examination showed on the outside a loose layer of connective tissue, the fibres of which did not run in any particular direction. Internal to this was a layer of felted connective-tissue interlacing and a very rich supply of blood-vessels, richer than that which is normal in the adventitia. Most of these fibres were of the yellow elastic variety and interlaced in the general trend of the artery. Internal to the adventitia was the tunica media, consisting of muscular fibres, elastic tissue, and a great abundance of inflammatory cells. Internal to this was the inner elastic lamina. Within this there was a zone which at some of the points of its circumference was composed of mature connective-tissue fibres; at others it consisted of a pool of blood. Internal to this was a dense mass of muscle fibres. The fibres of the media were swollen and granular and not in a good state of nutrition. Internal to this was the inner elastic lamina of the invaginated portion of the artery and the lumen of the tube was filled with a clot. There was some evidence of connective-tissue growth in this clot. The union between the artery ends was incomplete.

Experiment No. 12.—Right common carotid of calf, same as used in Experiment 11. Operated May 3, 1896. Resection of one-half inch of artery, united with three invaginating sutures. Three peripheral sutures were made as above; but very little bleeding followed the operation. Sheath was drawn over artery. Clamps used as temporary hæmostatics, as above. The skin was approximated with catgut. There was no swelling or tumefaction after operation, as on opposite side.

June 1, 1896, one inch of artery at point of union was removed and artery was again sutured (see Experiment 13). But little inflammatory deposit was found around the seat of wound. Primary union of skin and subcutaneous tissue had taken place. Some reactive inflammation had taken place around the artery. Water passed freely through the artery when removed.

Microscopic examination: The section showed a mass of granulation older at the periphery than at the centre. The inflammation was somewhat nodular; there were some places where it was more intense than at others. In the centre there was a small opening, in the walls of which there were young embryonal cells. The artery was being obliterated by a general arteritis.

Experiment No. 13.—June 1, 1896, the second experiment on right common carotid of calf. In the first experiment of May 3d one-half inch of artery was removed. On June 1st the specimen was removed, one inch being taken out at seat of union. The artery was then sutured end-to-end with interrupted silk suture, without invagination. There was some tension on the sutures and the artery was somewhat diminished in size. The left carotid had previously been removed and the ends ligated. When the clamps were taken off there was no hemorrhage at the line of suture. The calf rallied after the operation and was perfectly well.

Post-mortem, June 5th, four days after operation: Primary adhesion of wound; the artery was carefully dissected out. There had been no hemorrhage around the line of union; the vessel was patulous; its lumen was slightly diminished. A small white exudate covered the line of union. The sutures were not exposed in the lumen of the artery, being covered by the exudate. The intima had not been fractured at the point where the clamps were placed.

Experiment No. 14.—August 26, 1896; brown dog, weight forty pounds. Median abdominal incision. The abdominal aorta was located just above its iliac bifurcation and exposed for two inches. Billroth clamps were placed in position. A transverse incision was made in the artery for two-fifths of its circumference. It was sutured with kangaroo tendon involving all the coats. There was some hemorrhage

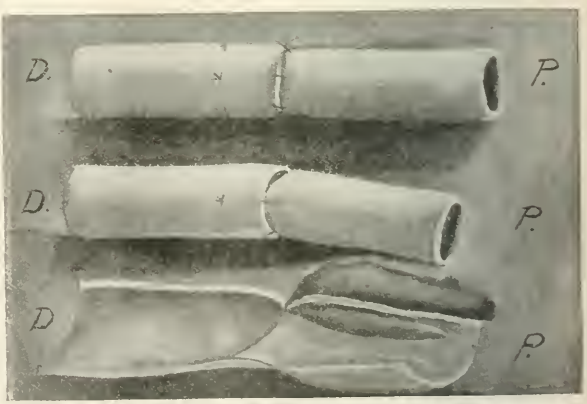

Fig. 6.—Shows Perforation of Artery and Line of Union after Removal of Clot in Experiment No. 14.

after removal of the clamps. An additional superficial suture was inserted. The retro-abdominal peritoneum was closed over the artery. The abdominal wound was closed with silkworm gut sutures. The dog died three days after operation.

Post-mortem: Abdominal cavity filled with blood;

no peritonitis. An opening was found in the posterior abdominal peritoneum leading to the vessel. The vessel was removed. A clot of considerable size existed in the retroperitoneal space around the opening of the vessel; this was continuous with a small clot within the vessel shown in gelatin specimen No. 2 (Fig. 5). The clot on the inner side of the vessel measured three-eighths inch in length and one-eighth inch in diameter. It was not adherent to the wall of the vessel but was continuous with the clot from the outside. There was some discoloration of the intima from the upper clamp and a roughening of the surface at that point, but no clot was formed. The lumen of the artery above and below the vessel was free. The kangaroo tendon was softened and would not support its own weight, which accounted for the hemorrhage. On the inner surface of the artery were seen the openings of the small arteries, which were free. There was a ragged transverse opening, which was gaping widely at the centre. The point of adhesion of the clot was without the arterial wall. The remnants of the sutures were seen penetrating the intima. One and one-half centimetres above there was a point of ecchymosis. One centimetre above that a second point of ecchymosis could be seen, the result of the clamps. The ecchymotic patches were transverse in their long diameter and three-fifths centimetres wide. In the one next to the incision there had been rupture of the deep arterial coats, but the intima had been preserved except at one small point; in the other fracture of the intima and media had taken place. There was no clot at either of these places (see Fig. 6).

Experiment No. 15.—Black dog, weight forty pounds. Operated August 26, 1896. Median abdominal incision. Exposure of abdominal aorta two inches above its iliac bifurcation. A longitudinal incision was made in the artery one centimetre in length. Sutured with kangaroo tendon taken from same bottle as for Experiment 14. Arterial clamps were placed on artery, as above. Slight hemorrhage from the wound after the clamps were removed. This was controlled by digital pressure for one minute. Posterior peritoneum was not sutured over artery. A great deal of difficulty was experienced in retaining the artery in an elevated position sufficient to admit of suture, as the dog was fat and his abdomen deep. The dog died forty-eight hours after operation.

Post-mortem: Abdomen full of blood. Loose large clot existed in retroperitoneal space. The artery was removed for several inches above and below the clot: its lumen was free. There was no clot on the inner side. The kangaroo tendon was completely disintegrated. Cause of death, hemorrhage.

The general appearance of the artery was normal. Small arteries were seen emerging at different points. The line of incision could be readily recognized. Its edges were roughened and projected about one millimetre into the lumen of the vessel. The ragged incision extended throughout the wall of the artery; in it were seen the remains of the tendon suture. There was no evidence of regeneration; that is, no reaction process in the walls of the vessel. There was some fibrinous deposit on the roughened edges; no tendency to coagulation on the inner side of the artery. About one centimetre below the line of incision was a small ecchymosis where the intima was roughened and endothelia were absent: there was also a loss of substance, showing a fracture of the intima. There was a small fibrous deposit on this area.

Experiment No. 16.—September 6, 1896: black male dog, weight seventy pounds. Transverse incision dividing one-half of the anterior wall of the abdominal aorta: the opening was closed by a continuous suture of silk with round needle involving all the coats of the artery. After the clamps were removed there was bleeding from the angle of the wound; an additional suture was applied without the aid of the clamps. After this was done the bleeding ceased and the abdominal wound was closed. The dog died fifty-four hours after operation.

Post-mortem revealed the abdomen full of blood. An examination of the artery showed three-fourths of the line of suture approximated and surrounded by a clot. The last suture which was inserted in the angle of the wound was shown to have included on one side only the tunica adventitia, it did not grasp the media nor the intima. This suture gave way and from this point hemorrhage took place. There was no regenerative reaction in the intima around the punctures made by the needle. There was no clot formed on the silk that was exposed in the lumen of the vessel. From

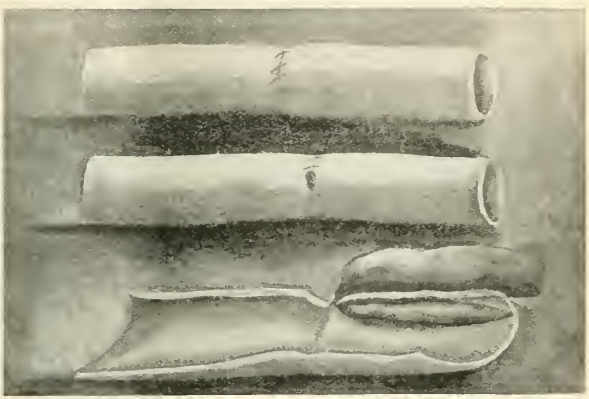

Fig. 7.—Shows the Position of Sutures in Edge-to-Edge Union of End of Artery and Defect in Line of Suture in Experiment No. 6.

the ragged edge at the position of penetration a small clot was adherent and suspended within the artery, but not adherent to the intima; it was continuous with the external clot. This clot was about a centimetre in length and a millimetre in thickness; smooth on its outer edge. The endothelium in the immediate neighborhood was milky white and somewhat roughened.

Experiment No. 17.—September 6, 1896; black and white female dog, weight forty-five pounds. Complete transverse section of abdominal aorta. Continuous silk suture with three needles; edge-to-edge union of artery (Fig. 7). The stitches were closely applied. After the clamps were removed free hemorrhage took place, particularly at one point, where the beginning and end of the sutures met. The clamps were reapplied and one stitch was placed at this point. It would have been better if I had made the final stitch overlap the primary stitch, as the artery was contracted when the arterial pressure was off; while the first and last stitches appeared to be close together then, when the artery dilated they were quite a distance apart. The abdominal wall was closed with silkworm gut.

The dog died September 12th. Post-mortem showed silkworm gut to have cut through; absence of organic union over entire length of abdominal incision. An external fistula communicated with the peritoneal cavity. The peritoneal cavity contained a large quantity of pus and some blood. There were many adhesions and a clot of considerable size around the iliac vessels. A clot also existed on the right side of the incision

ochind the iliac vessels. On the inner side of the artery the clot was adherent and sealed over the line of union. The clot was not adherent to the intima but adherent to the line of union. A slight thin white clot had formed over the point where the temporary hæmostatic forceps were placed during the operation. There were no manifestations of inflammatory reaction or regeneration in the intima; a small thin clot extended from the point of injury by the hæmostatic forceps above down to the line of union. A small flat coagulum extended from the line of union down to the injury of the intima made by the lower hæmostatic forceps. On the outside of the point where the hemorrhage took place the sutures were exposed. An opening one-sixteenth of an inch existed on the anterior surface of the vessel at the line of union communicating with its calibre and was partially occluded by a clot. This was the opening through which the fatal hemorrhage occurred. There was excellent union over the line of approximation. There was no clot in either of the iliac vessels. The intima was somewhat roughened over the entire distance between the position of application of both of the forceps. One of the stitches from the point where the hemorrhage occurred had cut through. There was a small perivascular clot around the position of approximation, and blood had burrowed between the tunica intima and media.

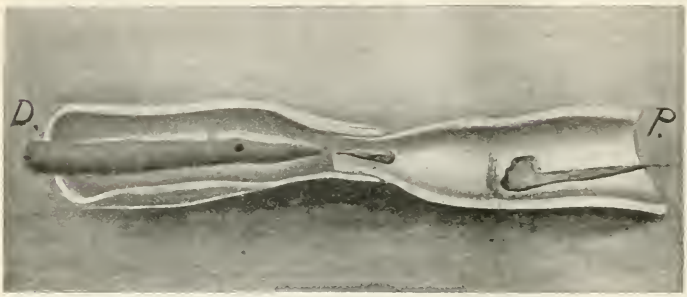

Fig. 8.—Shows Contraction of Artery at Line of Suture, with Clots on Proximal and Distal Sides, from Experiment No. 19.

Experiment No. 18.—September 6, 1896; black dog, weight sixty-five pounds. Complete transverse section of abdominal aorta. Invagination of proximal into distal end with three internal sutures; eight external interrupted sutures were inserted, including all of the coats of the artery in each. When the clamps were removed profuse hemorrhage took place from one point. Clamps were replaced and an additional suture was inserted; the clamps were again removed, with no escape of blood. Abdominal wound closed with interrupted catgut sutures. On the sixth day after operation there was some bleeding through abdominal wound.

Dog died on the eighth day. Post-mortem: General suppurative peritonitis; a complete thrombosis of the artery had taken place at the site of suture. There was some blood in the peritoneal cavity; suppuration around the seat of arterial approximation. Two of the sutures had cut through. A thrombus occupied the vessel for two centimetres above the seat of injury, and two and one-half centimetres below; that is, between the points where the arterial clamps had been placed. The clot was adherent at these points and free in the vessel over the intermediate area.

Microscopic examination: A clot had formed, completely filling the lumen of the vessel. The surface of the clot was filled with round cells and developing connective tissue. The connective tissue developed from the intima in such a manner as to map the clot off into plaques of round cells mingled with leucocytes, and connective-tissue cells surrounded by borders of connective tissue. The intima was markedly thickened, the fibres being separated by bands of young connective-tissue cells. The spaces between the fibres filled with cells were broader than the fibres themselves. The same was the case in a lesser degree in the media and adventitia. Union had not progressed very far; it was not firm and tore apart upon slight manipulation. The granulation tissue by which it was held together was in the round-cell stage.

Experiment No. 19.—October 27, 1896; merino sheep, weight ninety pounds. Transverse incision of left common carotid artery. Compression of artery with strands of gauze. Proximal invaginated into distal end in the usual manner. Four needles threaded with silk were used. After compression there was some hemorrhage; as one of the sutures had cut through the wall of the artery, another suture was inserted in its place. The artery was very small for invagination.

The sheep died twenty-eight hours after operation, from cerebral anæmia. See Experiment 20. Post-mortem: In the left common carotid artery the line of suture was scarcely discernible, it being covered with a cleavage; there was a very small clot on proximal side of suture (Fig. 8). There was injury to the intima by the peripheral sutures. Clot on distal side was not adherent except at position of approximation. Clot on proximal side extended beyond the position of division of the artery one-third inch from the point of approximation. The walls of both arteries were firmly adherent. The canal was almost completely occluded by the invaginated portion. Line of union was a little difficult to locate with the naked eye. The calibre of the vessel was so small that the clot at the point of union was about one sixty-fourth of an inch in diameter.

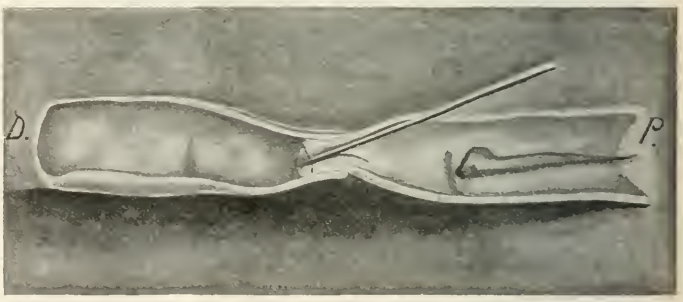

Fig. 9.—Shows the Marked Diminution in the Size of the Lumen of the Vessel at the Point of Approximation, from Experiment No. 20.

Experiment No. 20.—Same sheep as in Experiment 19. Right common carotid artery. Transverse incision; end-to-end invagination. Artery invaginated with four needles threaded with silk. Adventitia was carefully peeled off. At one point hemorrhage took place, but was checked by an additional suture. Sutures were dipped in beeswax before insertion.

Post-mortem: The artery on the right side was thrombosed for three-eighths of an inch on proximal side and three inches on distal side of the line of suture. The clot was not adherent to the wall of the vessel above or below the line of approximation, showing that it originated at the line of union. There was no hemorrhage between the adventitia and the media where the former overlapped the line of union, showing it was completely sealed. The artery was very much diminished in size where the four invaginated sutures were tied. There was a discoloration and apparently a rupture of the intima at the position where the temporary hæmostatic ligature was placed. A small clot existed on the proximal side of the suture; both layers of both walls were firmly adherent, requiring considerable force to separate them. The agglutination of the walls was very firm. The calibre of the artery was diminished to the size of a knitting-needle at the position of invagination (Fig. 9). The clot formed from the end of the intussusceptum. One of the stitches crossed on the inside of the artery, to which the clot was firmly adherent. There was a slight roughening of the intima where the temporary ligature had been attached, and a small clot one-half of an inch in length formed at that position.

Experiment No. 21.—October 29, 1896, sheep, weight about eighty pounds. Excision of one-third inch of left common carotid. End-to-end continuous suture of wall of artery which was not invaginated; sutures waxed while wet. Considerable hemorrhage: three additional stitches inserted. Hemorrhage controlled by forceps while operating. Adventitia sutured over line of union; sheath replaced and sutured. Irregular active rhythmic contraction of coats of wall of artery noted after removing adventitia.

Post-mortem: November 3, 1896, left common carotid. Clot on distal side occluding artery. Artery contracted and bent at a right angle. There had been hemorrhage around the line of union; no suppuration. Line of union was difficult to make out. Specimen retained without opening the lumen of vessel.

Experiment No. 22.—Same sheep on same day as Experiment 21. Oblique incision in right common carotid artery, one-third inch long, was made; continuous silk suture including all coats. When the adventitia was removed there was a rhythmical contraction of the artery, the same as in an intestine when injured. Artery diminished one-third in diameter (see Fig. 10). No hemorrhage followed the removal of forceps.

Post-mortem: November 3, 1896, right common carotid. Clot extended one inch to the proximal side and one-half inch to the distal side of the line of suture. This was very small; it had formed over the position of suture, but was not adherent to the wall of the vessel. It did not completely fill the vessel and extended upward from the line of union to the line of fracture in the intima, where it was again adherent. Over one-half of the length of union the silk was covered so that it could not be seen. The artery had been fractured by the clamp.

Experiment No. 23.—Sheep. Operated October 31, 1896. Resection of one-half inch of left common carotid; artery invaginated with four double-needled sutures. The adventitia of the proximal side was torn back; then the proximal was drawn into the distal, bringing the media of the proximal in contact with the intima of the distal. The edge of the intussuscipiens was then approximated with two sutures to the periphery of the intussusceptum. The adventitia of the intussusceptum was then drawn over the line of union and sutured to the periphery of the intussuscipiens, making the order of the coats overlapping each other from within outward: two internal coats of proximal, three coats of distal, adventitia of proximal.

The sheep used in this and the following experiment died November 14th. Post-mortem of left common carotid. Thrombosis at the position of union and a fracture of artery on the proximal side where the hæmostatic forceps had been placed, but no clot adherent to it. On the distal side there was also a fracture of the artery with a clot adherent. A thrombus which did not completely fill the artery existed from this point to the line of suture. The two coats were firmly adherent and could not be separated without laceration. There was a firm connective-tissue deposit outside completely covering the line of union, so that it could not be recognized. There was no hemorrhage around the seat of union. The greatly diminished size of the artery at the position of invagination was, I believe, the cause of the formation of the clot. Only one suture was exposed outside the exudate and that was the one used to draw the adventitia over the line of approximation. Specimen given to pathologist for sections.

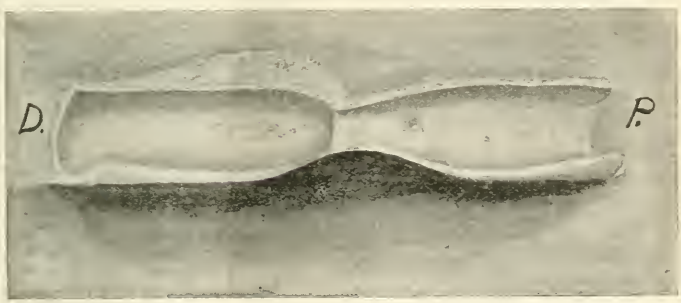

Fig. 10.—Shows the Usual Contraction at Seat of Approximation. See Experiment No. 22.

Experiment No. 24.—October 31, 1896: same sheep as in Experiment 23. Right common carotid artery. A V-shaped incision of one-fourth of an inch on each side was made. It was closed with a continuous suture of six stitches involving all coats of the artery. The sheep was very sick for two days before death, showing all symptoms of sepsis.

Post-mortem, November 14th, fourteen days after operation: All of the tissues of the neck were infected. There was an absence of union in a portion of the skin and a most offensive discharge of pus and blood. The tissues of the neck were so much inflamed that their recognition was difficult. A clot the size of a walnut existed on the anterior side of the artery at the line of suture. A thrombus filled the proximal side for a half-inch from the opening in the vessel. The opening had increased to three-fourths of an inch in length on the anterior surface of the vessel, showing that there had been an elongation of the opening by a necrosis of the wall of the vessel at the line of suture.

The clot had a very offensive odor; pus surrounded the wall of the artery. The distal end of the artery was closed by a thrombus up to the head. This specimen shows the destructive effect of infection in arterial suture better than any of the former ones. Cause of death, sepsis.

Experiment No. 25.—November 2, 1896; sheep, weight about seventy pounds. Resection of one-fourth inch of right carotid artery; invaginated; continuous external suture. Artery very small; adventitia not removed; silk had been boiled in a saturated solution of oxalate of ammonium and waxed. Sheath closed over artery with a few catgut sutures.

Post-mortem, November 30, 1896: There was no clot on proximal side of suture, no infection at point of suture. A white organized thrombus existed, filling the vessel. The exact line of union could not be seen when the thrombus was removed. Thrombus extended for one-half inch on the distal side of the line of suture. Specimen was given to Dr. Evans for examination. Union of ends of artery from a macroscopic standpoint was perfect.

Experiment No. 26.—November 2, 1896; same sheep as in Experiment 25. Transverse incision of one-half the circumference of the right jugular vein. Opening closed with a continuous silk suture, which was oxalated and waxed. The wall of the vein was very thin and required considerable care to prevent its laceration with the suture. It was diminished considerably in size by the suture.

Post-mortem, November 30, 1896: Periphlebitis existed at the site of suture. There was no thrombus in the vein. The diameter of the vein at the point of suture was about one-third of its diameter above and below. A white exudate covered the line of suture.

Experiment No. 27.—November 2, 1896; same sheep as in Experiment 25. Complete division of left jugular vein; edge-to-edge union with continuous oxalated waxed silk suture. Wall of vein was very thin. The continuous suture contracted the vessel to about one-half its normal size. There was but little bleeding after the digital pressure which had been used for hæmostasis was removed.

Post-mortem, November 30, 1896: Periphlebitis of slight degree existed; no œdema or evidence of infection. When the vein was opened, it was found that there was a complete occlusion by adhesion at the line of suture. There was not the slightest thrombus on either the distal or proximal side of the suture. The thickening from the exudate at the line of suture was scarcely perceptible. The vessel appeared to have retained its normal diameter on the proximal and distal sides of the suture.

Experiment No. 28.—November 3, 1896; sheep. Resection of one-third inch of left common carotid. End-to-end approximation of artery with continuous oxalated waxed silk suture. There was considerable hemorrhage from artery when clamps were removed, which ceased with slight pressure. Adventitia was not removed.

Post-mortem, November 30, 1896: The diameter of the artery above and below the point of approximation was one-eighth of an inch. The artery was thrombosed for one inch on distal side and three-fourths of an inch on proximal side of suture. The sutures were infected; the lumen of the artery was entirely obliterated.

Experiment No. 29.—November 3, 1896; same sheep as in Experiment 28. A semilunar piece one-half inch long, involving one-half the circumference of the left jugular vein, was excised. The opening was closed with a continuous oxalated waxed silk suture; but very little bleeding after pressure hæmostatics were removed.

Post-mortem, November 30, 1896: A thickened inflammatory cord existed at the site of the suture. There was some œdema of the surrounding tissue; about one-fourth of the lumen of the vein was patulous. A white exudate covered the sutures within the lumen of the vessel. There was no thrombus.

Experiment No. 30.—November 8, 1896; black dog, weight about forty pounds. A transverse division through all coats of one-third of the circumference of the abdominal aorta, one inch above its bifurcation, was made. A continuous silk suture of seven stitches was inserted, including all of the coats of the artery. The silk had been boiled in a saturated solution of oxalate of ammonium. The adventitia was peeled off the artery. The suturing was done with a full curved sharp needle with cutting edges. The needle was inserted so closely that three of the openings cut into one; some bleeding took place from this point when the clamps were removed. Two additional stitches were required. The abdomen was closed with two rows of continuous catgut sutures.

The dog was killed December 5, 1896, twenty-seven days after operation. The abdominal wound was entirely closed. The dog had increased much in weight. There was no peritonitis; a slight elevation of connective tissue on the anterior surface of the artery at the site of suture was noted. The artery was divided; it was very slightly contracted in size at the line of suture. The silk was covered over by a thin white fibrous exudate. There was a slight depression of the surface at the site of union. The arterial wall was perfectly healthy above and below, showing none of the effects of the compression clamps. From a macroscopic point of view the greatest support given the artery was from the connective tissue on the outer wall. Specimen was given to pathologist for examination. This specimen illustrates beautifully the process of repair when the field is kept aseptic.

Experiment No. 31.—November 8, 1896; black hunting-dog, weight thirty-five pounds. Left common carotid; a longitudinal incision two centimetres long was made. It was closed with a waxed silk suture which had been boiled in a saturated solution of oxalate of ammonium, and included all the coats of the artery. The technique of the operation was the same as in the other experiments. Seven stitches were inserted in the artery; there was no hemorrhage after hæmostatics were removed.

Post-mortem, November 24th: A small clot was found, one-third the size of the calibre of the artery, not adherent to it except at point of infection. A pocket of pus, one-fourth of an inch in diameter, existed around the point of suture, showing that the stitches had been infected. On the proximal side of the suture the clot filled the vessel for one-fourth of an inch and was adherent. A small free clot existed for three-fourths of an inch on the distal side.

Experiment No. 32.—November 8, 1896: dog same as in Experiment 31. Both carotids were exposed by an incision deep in the neck. A longitudinal incision, one and one-half centimetres long, was made in the right common carotid. It was closed with a continuous waxed oxalated silk suture, including all of the coats of the artery. There was no hemorrhage when the hæmostatics were removed. The incision was closed with a continuous suture of catgut.

Post-mortem, November 24th: The dog died on the evening of November 23d. A sinus leading from the external opening was traced down to the opening in the vessel. The clot around the vessel had suppurated, and the sutures had cut through the vessel. There was no thrombus within the lumen. A small white clot was adherent close to the margin of the wound; there was no effort at definitive union. Cause of death, hemorrhage.

Experiment No. 33.—November 10, 1896: calf,

eight months old. A resection of one-third inch of right common carotid was made. Invagination by three internal sutures and seven external sutures. The artery was the size of the common femoral in man: no blood escaped: sheath around artery was sutured with catgut; no drain. The invaginating sutures in this case were inserted differently from those in any of the preceding experiments. They included only the adventitia and media of the invaginated portion, and when tied were not exposed in the lumen of the artery in any place (Fig. 11). By this method the size of the artery was not diminished in the same degree as it had been in any previous experiment. It can be seen that by this method there was no foreign body left in the lumen of the artery, as had been done in the previous method of invagination, and therefore there was less likelihood of thrombosis. The peripheral sutures included only the media and adventitia. Temporary hæmostasis was produced by a fine strand of gauze tied firmly around the artery. Specimen removed December 5th. Primary union of the external wound had taken place: an extensive induration two and one-half inches in length by one and one-half inches in diameter was found at the site of approximation. This mass was carefully dissected out and the artery was found patulous at each end, although considerably diminished in size. On opening the mass it was found to be a pus pocket, about three-fourths of an inch in diameter. In the centre were found the necrotic ends of the artery and the sutures. The infection had occurred at the suture. The vessel was thrombosed for one-third of an inch on either side of the abscess. The ends of the artery in which the sutures were inserted were well preserved, though the vessel had been amputated by the inflammatory action on either side of the abscess. The thrombi were very firmly adherent to the intima.

Experiment No. 34.—November 14, 1896: large black calf, about eight months old. A transverse division of right common carotid was made: end-to-end union by invagination: kangaroo tendon furnished by Dr. Longyear, of Detroit, was used. Three invaginating and six external sutures were inserted, as in Experiment 32. No escape of blood after removal of clamps. Adventitia was peeled off and returned over the line of suture. Fascia and sheath were sutured over the artery. A strand of gauze was tied around the artery to produce temporary hæmostasis. The vessel was a little larger than the common femoral in man. Pulsation was normal on the distal side of the approximation immediately after operation.

Specimen removed December 5th. There was no induration or inflammatory action around the site of approximation. Some connective-tissue formation outside the adventitia was found. There was but one suture exposed within the lumen of the vessel, and that for only a very small extent. When the vessel was opened, a thrombus existed on the proximal side of the line of union for one-half an inch, completely occluding the vessel. This was firmly adherent for the first half of that space; over the line of union and for one-fourth inch on the distal side the thrombus was not adherent; again it was adherent for one-fourth inch, occluding the vessel. It should be noted that the points of adhesion and formation of the thrombus were where the temporary ligatures were placed during the operation, showing that the injury done the artery by the ligature was the cause of the thrombus. The union between the two walls of the artery was firm. The kangaroo tendon appeared to be as hard and as firm as when it was inserted.

For convenience in treating the subject, arterial and venous suture, we will consider: (1) The pathologic histology of repair of blood-vessels. (2) The class of arteries and veins amenable to suture. (3) The degree of destruction that may exist and still leave the vessels within the range of repair by suture. (4) The technique of vessel suture. (5) The prognosis of arterial and venous suture.

Pathologic Histology of Repair of Arteries and Veins.—That the clinical aspect of the subject may be better appreciated, let us first consider the histology and physiology of the vessels and blood.

Structure and Properties of Arteries and Veins.—The arteries and veins of the body are the channels through which the blood is carried to and from the tissues and organs. The thin-walled capillaries bring the blood into intimate relation with the cells by transudation and migration.

The arteries are distinguished from the veins by their thicker walls due to the greater development of smooth muscular and elastic tissue. The middle coat of the artery is especially thick, while the outer coat is relatively thin.

The arteries consist of three coats, and are derivatives of the mesoblast. The tunica intima, or inner coat, consists of a layer of irregular or oblong fusiform nucleated squamous cells forming the excessively thin transparent endothelial coat immediately in contact with the blood stream. These cells have oval nuclei and the long axis of the nucleus and cell is parallel with the long axis of the artery. The endothelial cells

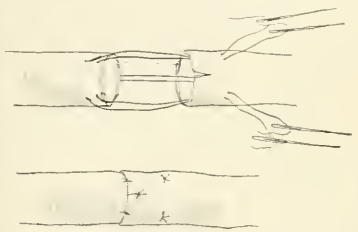

Fig. 11.—Shows Method of Insertion of Sutures in Experiment No. [illegible].

have no distinct blood supply, still they have the power of reproduction, and are possessed of marked potential reactive properties when disturbed mechanically or chemically. This was appreciated first by Jones, who showed in his experiments that on account of its regenerative properties it was necessary to injure the intima to produce successful ligation of the arteries. These endothelial cells are held together by a cement substance. Outside of these lies a very thin, more or less fibrous layer, sub-epithelial, in which numerous spindle or branch-shaped protoplasmic cells lie embedded, with a corresponding system of plasma canals. Outside of this is an elastic lamina. In arteries of medium size it is a fenestrated membrane, while in the largest arteries there may be several elastic laminæ, or fenestrated membranes, mixed with connective tissue. In middle-sized arteries and in larger arteries a few non-striped muscular fibres are disposed longitudinally between the elastic plates or laminæ along with the circular muscular fibres of the middle coat. They may act so as to narrow the artery, but they may also aid in keeping the lumen of the vessel open and of uniform calibre. It is not probable that when they act by themselves they dilate the vessels. The nourishment of the intima is entirely independent of the media and adventitia. Its nutriment is received directly from the blood within the artery.

The tunica media, middle coat, or muscularis, contains much non-striped muscle, which in the smaller arteries consists of transversely disposed non-striped muscular fibres lying between the endothelium and the adventitia, while a finely granular tissue with a few elastic fibres forms the bond of union between

them. As we proceed from the very small to the larger arteries, the number of muscular fibres becomes so great as to form a well-marked fibrous ring of non-striped muscle in which there is comparatively little connective tissue. In the large arteries the amount of connective tissue is considerably increased, and between the layers of connective tissue numerous thick fibres or fenestrated laminæ are concentrically arranged. From a clinical standpoint it can be seen that this coat is composed of histological elements which have very little, if any, power of regeneration. Repair of injury to these elements is accomplished by the formation of new connective tissue. Balance and Edmunds claim that the vasa vasorum penetrate this coat. It is certain from the experiments of Bruci (Pisa, 1893) that the media receives its nutriment from the adventitia either by vessels or nutrient canals, as he demonstrated that a necrosis of the media took place when the adventitia was removed and prevented from readhering by wrapping gutta percha around the vessel; but the intima was not affected by this procedure, except to show evidence of increased proliferation. When the adventitia is torn off and immediately replaced, the alteration of the muscularis is scarcely discernible.

The tunica adventitia or outer coat in the smallest arteries consists of a structureless membrane with a few connective-tissue corpuscles attached to it. In the somewhat larger arteries there is a layer of fine fibrous elastic tissue mixed with bundles of fibrillated connective tissue. In the arteries of medium size and in the largest arteries the chief mass consists of bundles of fibrillar connective tissue containing connective-tissue corpuscles. The bundles cross each other in various directions and fat cells often lie between them next the media; this accounts for the loose adhesion of the two coats and also for the ease with which the adventitia may be peeled off from the media. There are numerous fenestrated and fibrous elastic laminæ. In the medium-sized and small arteries the elastic tissue next the media takes the form of an independent elastic membrane. It contains blood-vessels to the wall, the vasa vasorum, which are supplied from the nearest branch and not from the main trunk of the artery; these vessels usually extend to the media, never to the endothelial cells. It also contains nerves, the small axis cylinders extending through all the coats to the endothelial cells and intercellular substance.

The veins have the same anatomical construction, except that the wall is thinner on account of the smaller amount of non-striped muscle and elastic tissue; there is no noticeable primary contraction of the veins when injured, as there is in the arteries. They are more extensile under the same strain. The adventitia is usually the thickest coat.

The large blood-vessels are therefore cylindrical tubes composed of several layers of tissue, more especially elastic tissue and plain muscular fibres. One of the important properties is contractility of the vascular wall, by virtue of which the blood-vessels may be elongated or shortened, the diameter of the vessel may be dilated or contracted and the supply of blood to a part altered; this contractility plays no small part in the surgery of the vessels. Their elasticity is great, that is, they offer little resistance within certain limits to any force employed to distend or elongate them; if the force be uniform the blood-vessels rapidly regain their original size and form, after the force distending them is removed.

The extent to which the arteries may be stretched has not been accurately estimated. Veins may be stretched fifty per cent. without passing the limit of their elasticity; *i.e.*, when a vein is freed from its adhesions to surrounding tissue, fifty per cent. of the distance may be removed and still the vein possess sufficient elasticity to be approximated. From personal observation I have found that a large portion of carotid arteries could be removed and the ends approximated without difficulty. The internal pressure which a vessel will withstand is very much greater than the normal arterial pressure to which it is subjected, showing that, in the process of surgical repair, a wall much more feeble than the normal wall of the vessel is sufficient to hold the blood in control. Volkmann found the carotid of a sheep would rupture only when fourteen times the normal pressure was put upon it. The carotid of a dog withstood fifty times the normal blood pressure; the jugular vein about one-half of this (Greheut and Quinquand). It may be deduced from the above that there is little danger of aneurism at the point of union, even if the walls are somewhat weaker than normal.

Thrombosis and Coagulation.—Blood in direct contact with living unaltered blood-vessels does not coagulate (Hewson, Brücke). Coagulation takes place within an injured blood-vessel after death of the leucocytes. The action of the paraglobulin on the fibrinogen in solution in the plasma produces coagulation, if salts of calcium be present. Paraglobulin is believed to be the product of disintegration of cellular elements of blood, principally leucocytes and blood plates. Peptones injected into the blood of a dog do not permit of the interaction of lecethin, and thereby prevents coagulation (Wooldridge). Freund believes that the death of the red blood corpuscle causes conditions which produce coagulation. He showed that blood collected in glass vessels smeared with vaseline did not coagulate for a long time if decomposition were prevented. Experiments further show that apparently unimportant changes in the condition of the vessel wall may cause coagulation; this result is confirmed by the observations by many pathologists. "All observers are agreed," writes Thoma, "that the solution of the red blood corpuscle causes coagulation, although they differ as to the explanation." It is probable that the splitting of the fibrinogen molecule is produced by the nucleo-proteid and the thrombosin thus formed combines with the calcium; fibrin is a salt of calcium. Albertoni observed that if tryptic pancreas ferment or histon be injected into the blood of an animal, the blood would not coagulate. The three factors necessary for coagulation are fibrinogen, nucleo-proteid in considerable quantity, and calcium salts. The coagulation is favored by contact with foreign substances of all kinds, but only when it adheres to them. Blood does not readily coagulate in contact with bodies covered with fat or vaseline. Waxed sutures prepared in oxalate of ammonium should, therefore, be used when the intima of an artery is penetrated. We have been taught that a roughening or irregularity in the wall of an artery would produce coagulation thrombosis. My observations on arteries lead me to believe that this statement is erroneous and that thrombosis occurs only when a foreign body is left in the artery to which the blood adheres, or when an infection is present with the foreign body, causing the death of cellular elements of the blood. The theory that injuries to the intima, *per se*, do not produce thrombosis is supported by Porta's observations that thrombosis of the artery was absent in fourteen per cent. of the ligations made by him where the intima was injured, and Schumann found experimentally that thrombosis occurred in a very much smaller percentage of cases. Senn observed that a clot was not formed on the proximal side of ligatures in veins, but always on the distal side. These show that trauma of the ligature, in itself, does not produce coagulation in the vessel.

As a proof that an irregularity in the wall of an

artery does not produce thrombosis, we have the clinical fact that arteries penetrated by bullets rarely ever thrombose. They almost always form dissecting aneurisms, and there is no tendency to coagulation within the vessel at the seat of the injury, nor below that point if sufficient of the wall remains to guide the current of blood into the distal portion. In Case II. of this paper, notwithstanding that the artery had been completely penetrated by the bullet, leaving the irregular edges of the arterial coat projecting into the lumen of the vessel, there was not the slightest tendency to the formation of a clot within the vessel nor on the ragged edges of the wall. This observation is supported by the clinical course of traumatic aneurisms, and numerous cases may be cited to support this theory, that the roughened edges do not produce coagulation. There is no doubt that even a considerable destruction of the intima does not always cause thrombosis, and that this process is lessened if the calibre of the vessel is reduced to certain limits in accordance with Thoma's histo-mechanical principle. Virchow, O. Weber, Paget, and Billroth believed that after ligation of the artery its permanent obliteration is produced by thrombosis and vascularization of the thrombus, and that tissue proliferation within it proceeds from the white blood corpuscles. Rokitansky showed that primary adhesion and definitive occlusion can take place independent of thrombosis. Senn verified this by his experiments. Kocher in 1869 proved that a ligature with primary adhesion of the endothelium would produce closure of an artery. This was further sustained by Lister, Baumgarten, Raube, and others. Waldeyer sustained the belief that the endothelium and subendothelial layer take an active part in producing adhesion of the wall of the vessel after ligation, that the intima receives its blood supply from the capillaries of the media, and that organization takes place from the endothelial lining which forms the basis of a new connective tissue.

Scarpa, recognizing that the endothelial coat of the intima is a derivative of the mesoblast, as the other serous surfaces, the peritoneum, pleura, pericardium, dura, etc., attributed to it the same physiological properties of regeneration. Its reaction to irritants is very much less than that of the peritoneum and much more than that of the dura, being about midway between the two.

The union between the walls of arteries after ligation takes place more rapidly without the formation of thrombus, that is, a thrombus is a foreign body and retards organic union in arterial approximation, whether with ligature with intent of definitive occlusion, or with suture with the purpose of definitive union of the walls. The former was well recognized by Baumgarten. The endothelial cells increase in number, producing long spindle cells and broad embryonal connective-tissue cells from beneath them (Raab). If vessel walls the same as peritoneal surfaces be brought in close approximation after irritation, they adhere primarily through cell proliferation from the intima by the process of budding of endothelial cells and division of connective-tissue cells. The remaining coats of the vessels assist in the definitive organization and vascularization of these adhesions, that is, the media is penetrated by vessels from the adventitia, and capillary loops are formed and joined until organic union is complete.

The subsequent changes in the thrombus are divided into five classes: (1) Hyaline-granular transformation. (2) Organization or replacement by connective tissue and re-establishment of the calibre of the vessel. (3) Calcification. (4) Simple softening. (5) Puriform liquefaction. After an artery has been thrombosed, the thrombus may entirely disappear and continuity of the canal be established. Its absorption is produced by the endothelia of the vessel covering the thrombus and the formation of connective-tissue cells. This gradually produces contraction of the thrombus, as shown in Figs. 195, 196, and 197, page 206, Thoma. Vessels from the vasa propria finally penetrate the intima and media of the vessel; absorption takes place, leaving the vessel patulous and its wall free (Thoma-Heuking).

Ischæmia, Collateral Circulation.—If the trunk of a large vessel be sutured and thrombosis takes place at the seat of union with complete occlusion of the vessel, the life of the part on the distal side will be jeopardized by the interruption in the circulation in proportion to the rapidity with which the circulation is shut off and the rapidity of the establishment of the collateral circulation, which plays an important part in retaining vitality and which requires time for its development. Permanent occlusion of an artery leads, as a general rule, to a permanent alteration and re-arrangement of the vascular system and generally to the development of collateral circulation (Thoma). After ligation of the main artery of an extremity, there is at first a disappearance of pulsation in all the branches. This will remain absent until such time as the circulation is re-established directly through the vessel or by enlargement and development of collateral branches. This can take place with great rapidity after ligation of a large trunk, as of the popliteal and femoral; the return of pulsation in the large vessels below can occur as early as twenty-four hours in the young, and proportionately later in older persons. The veins play an important rôle in the re-establishment of this collateral circulation, so that when the vein and artery are both occluded the danger of death to the extremity is much greater than when only one of them is occluded. Upon ligation of large arteries, corresponding to the first and second divisions, the vessel on the proximal and distal sides of the ligature contracts within five to ten minutes after it is tied, and remains permanently contracted, showing that the diameter of the artery is independent of the blood pressure (Thoma). When a blood-vessel is diminished in size, the tension on the wall at that point decreases. On the basis of this histo-mechanical principle, the invaginating method of the union of arteries diminishes the calibre of the vessel at the position of union, and therefore the tension diminishes while the blood current at that point increases in rapidity. The resisting power of the wall at the point of invagination is above normal, as the arterial coats are doubled at that point. From a mechanical standpoint the danger of rupture, dilatation, or thrombosis is lessened when the approximation has been made, as the diameter of the vessel at that point is smaller and the current more rapid. Experience shows that the gradual occlusion of a vessel always leads to the development of an increased collateral circulation; even the thoracic aorta comes under this rule. After suture of vessels there is a tendency to endarteritis obliterans. As this process is one of slow formation, it is one of minor importance as to the ultimate result of arterial suture. While the endarteritis is occluding the vessel, collateral circulation is being established and the danger of death of the part obviated.

The Effect of Ligature of Large Vessels.—The abdominal aorta has been ligated 10 times; one patient survived 10 days after the operation. The common iliac has been ligated 68 times (Lidell) with only 16 recoveries, a mortality of 76.5 per cent. In 31 cases of ligation of the femoral artery for aneurisms, hemorrhage occurred in 18, *i.e.*, 60 per cent., and was fatal in 12, or 40 per cent. (Balance and Edmunds), a mortality somewhat less than that of ligation of the common iliac, which is 67 per cent. Kammerer collected 28 cases of ligation of the femoral vein,

with gangrene in 2; in 22 cases of ligation of femoral vein and artery, gangrene followed in 12; in 178 cases of ligation of the artery alone, gangrene occurred in 25. Billroth in 1871 and 1872 found that he had secondary hemorrhage from 50 per cent. of large vessels ligated in continuity. Of 106 cases of aneurism of the common carotid, collected by Wyeth, with ligation on the proximal side of the aneurism, 67 terminated in recovery, a mortality of 35 per cent. In ligation for aneurism of the external carotid, according to statistics collected by the same author, there were 17 recoveries and 5 deaths, a mortality of 22 per cent. For aneurisms of the common carotid alone the death rate was 44 per cent. Lipp collected 130 ligations of the external carotid; only two died as a result of the ligation and these from extension thrombosis. In ligations of the internal carotid 13 to 18 per cent. succumbed to brain lesions (Fenger, Lyons, 1894).

The necessity of suturing arteries and veins depends upon their individual importance to the tissue on the distal side of the injured part; that is, we are called upon to suture arteries and veins only in cases in which by their obliteration there would probably be a necrosis or impairment of the vitality of the tissue supplied by them to such an extent that its normal functions would not be performed. Therefore in the upper extremities we shall not be concerned with the arteries below the brachial; in the neck not above the common carotid; in the abdomen we are concerned with injuries to the aorta, renal, splenic, hepatic, and iliac vessels. The greatest need for arterial suture exists after injury to the so-called terminal arteries, but they are the least accessible.

The Extent of the Arterial Resection.—I found that more than one inch of a calf's carotid could be removed and the ends could still be successfully invaginated with sutures. The vessels are very elastic, and when separated from surrounding tissues can be stretched to quite an extent. In dogs three-fourths of an inch could readily be removed and the vessel approximated and sutured. I believe the endarteritis in some of my experiments was caused by the stretching of the vessels and by denuding them of their connective tissue to such a large extent in order to elevate them. In many cases three inches of a vessel was freed from all connection before the hæmostatic forceps were applied. From my observations I cannot believe that a vessel can be repaired with safety when more than three-fourths of an inch is removed, except possibly in the popliteal space, Scarpa's triangle, or in the axillary space, where the position of the limb can be made to relieve the tension of the vessel.

The Technique of Arterial Suture.—For convenience I will divide these experiments on the arteries into four classes: (1) Longitudinal incision; (2) transverse or irregular wounds involving not more than one-third of the circumference of the artery; (3) transverse sutures involving more than one-half of the circumference of the artery; (4) complete division and resection of the artery not exceeding three-fourths of an inch.

The points to be considered in the technique are: (1) Complete asepsis; (2) exposure of the vessel with as little injury as possible; (3) temporary suppression of the blood current; (4) control of the vessel while applying the suture; (5) accurate approximation of the walls; (6) perfect hæmostasis by pressure after the clamps are taken off; and (7) toilet of the wound.

The arterial wall and its endothelium are products of the mesoblast the same as the peritoneum, and react excessively to irritation, but much more slowly than the peritoneum. Infection must be assiduously avoided, as we have not only the regenerative action of the vessel walls interrupted but also the action of the cellular elements of the blood forming a thrombus in their efforts to prevent the admission and advancement of sepsis in the vessel. If we have a suppuration outside the wall of the vessel, we may have a penetration of the infection to the inner wall and a thrombosis, failure of union from infection, or necrosis of the vessel when it is exposed to the action of the pus germs, as shown in Case I.

The vessel wall should be thoroughly exposed and the field prepared. The loose connective tissue should be freed with scissors and dissecting forceps for the required distance above and below the site of operation. If the operation be for a dissecting aneurism, it is well to expose the vessel above and below the tumor so as to control the hemorrhage; then open the aneurismal sac, remove the clot, expose the injured wall of the vessel, freshen the edges of the wound, and suture.

Control of Hemorrhage during Operation.—I find this is best accomplished by a delicate eight-inch Billroth forceps with a broad blade and graduated catch. The blades are first covered with a rubber drainage tube to prevent them from injuring the vessel; the forceps are closed just sufficiently to control the hemorrhage and hold the vessel in the correct position for approximation. If these forceps are not at hand a heavy twisted silk ligature may be used for the purpose; it must not be tied so firmly as to fracture the intima, and is best secured with a loop knot, so as to be readily removed when the operation is completed.

The Control of the Vessel while Applying the Suture.—The best instrument to use is the small rat-tooth catch forceps used by oculists, known as the fixation forceps. The intima should never be clasped with the forceps. The ordinary hæmostatic forceps should not be used in any place on the vessel, as it fractures the coats. The adventitia is sufficiently strong to control the vessel during the operation and is all that is necessary to be included in the fixation forceps.

Accurate approximation of the edges of the wound may be accomplished with needles and suture material. The former should be the same as are used by ophthalmologists and known as the full-curved sharp and round conjunctiva needles. The straight "floss needles," sizes 6 to 10, are very serviceable in experiments on the limbs or neck when the artery can be thoroughly exposed. The ordinary cambric needle may, however, be used, or, better, a fine cambric needle with an elongated eye. The suture material which I found most serviceable in my experiments was twisted silk. The needle and silk should correspond in size, so that the opening made by the former may be filled by the latter. Effort should be made in suturing lateral openings to have the sutures enter only the tunica adventitia and media, the tunica intima being avoided, as advised by Jassinowsky. The sutures should be inserted every one-sixteenth or one-twentieth of an inch; they should be interrupted, should enter the vessel one-sixteenth of an inch from the margin of the wound, and should not include the tunica intima. The reason for not penetrating the intima is not the danger of hemorrhage but of the endarteritis and obliterating thrombosis that might follow.

The ordinary double knot should be used, not too firmly tied. When the wound is transverse or irregular, care should be exercised in inserting the needle in parts that belong directly in apposition to each other. If one-half or a greater division of the artery be incised, the first suture should be inserted in the middle of the incision, then one at each angle.

[1] New York Medical Journal, May 10, 1891.

After the sutures are all inserted the compression forceps should be removed from the distal side first. If there should be hemorrhage from the needle punctures, a compression with the fingers or sponge for from one to three minutes will be sufficient to control it, as a small thrombus forms in each puncture. When it is possible after the approximation is completed, it is advisable to suture the sheath of the vessel, muscle, or fascia over the line of union, to give it additional support.

The field of operation should be thoroughly cleansed after the operation is complete and a gauze drain inserted. In bullet wound the bullet should be located and removed, as it might be a source of infection. An accurate approximation should then be made of all tissues with buried catgut suture. The drain should be removed in forty-eight hours.

Jassinowsky's experiments were confined to incised and irregular wounds involving not more than one-half the circumference of the vessel. I found that when more than half the vessel was destroyed, it was not advisable to suture the edges end-to-end, but to make a resection of the injured portion of the vessel and produce an end-to-end union by invagination. The sutures are inserted as shown in Fig. 11; two or three double-needled threads are prepared and inserted into the end of the proximal portion, including only the two outer coats; these are reinserted at regular intervals one-third to one-half inch above the end into the distal part from within outward; the threads are then tied and this invaginates the artery. In order to facilitate the invagination a small incision is made parallel to its long axis, extending from one-fourth to one-third of an inch; then four or five interrupted sutures are inserted into the intussuscipiens, binding it to the surface of the intussusceptum, the suture in the latter entering only the tunica adventitia and media. By this method we have secured a large surface contact of vessel, the proximal portion of the vessel being inserted into the distal. The arterial blood pressure tends to press the walls closer, thus preventing hemorrhage and favoring definitive union. By this method of approximation fewer sutures are necessary to secure blood-proof apposition.

In experiments it is important to use large-sized vessels, as the lumen of small ones is apt to be filled by a thrombus. The work is delicate; the vessels must be handled with all possible care, as every injury to the intima means inflammatory reaction for repair.

The veins may be subjected to the same treatment with better results.

The indications for operation are:

1. Injuries to large vessels in operation.
2. Injuries to large vessels from stab, puncture, bullet, or lacerating wounds.
3. Traumatic and dissecting aneurisms.
4. Sacculated, fusiform, and arterio-venous aneurisms (see Figs. 19 and 12, 13, 14 and 16).

In the first class of cases, *i.e.*, injuries to large vessels in operation, the injury to an artery, if less than two-thirds the circumference be involved, should be immediately repaired by suture. If more than two-thirds the circumference be injured, the division should be made complete and the invagination method used for approximation, care being taken that the invaginating sutures do not penetrate the tunica intima of the invaginated portion; that the external sutures do not injure the intima and are first inserted in the invaginated portion parallel to the long axis of the vessel and then inserted in the overlapping end (see Fig. 11). By this method the circumference of the artery is not diminished as it is when the suture is inserted transversely to the arterial axis. The sheath should be carefully sutured over the artery, as it gives additional support, and, if the general field of operation should suppurate, the line of union would thus be protected from infection. The field of operation should always be temporarily drained, as a blood clot prevents primary adhesions. When the edges of the arterial wound are ragged they should be freshened and clean cut before the suture is inserted.

In the second class of cases, *i.e.*, injuries to large vessels from stab, puncture, bullet, or lacerating wounds, the primary hemorrhage, as a rule, is not excessive, particularly when caused by bullet wounds, except when the abdominal aorta or renal vessels are involved, as the tissues are irregularly torn and overlap each other in such a manner as to prevent the escape of blood and favor the formation of aneurism; therefore, we have ample time to make proper preparation for the suture of the vessel. The wound may have existed for weeks or months with the dissecting aneurism and still be amenable to suture, as the opening in the vessel itself enlarges but little with time, the aneurismal sac being formed from the surrounding tissues and laminated coagula (see Fig. 12). The technique of suture in this class of cases should be the same as in the first, after the aneurismal sac has been enucleated and the opening in the vessel has been exposed and separated from its attachment to the wall of the aneurism.

In the third class of cases, *i.e.*, traumatic aneurisms

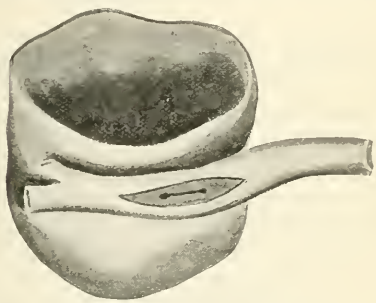

Fig. 12.—Shows Aneurismal Sac Formed from Connective Tissue and Laminated Coagula with no Enlargement of Original Opening in Vessel.

of long standing, we have the best variety of cases for arterial suture. The opening in the artery is usually small, the arterial wall is healthy, and a sufficient quantity of aneurismal stump may be retained to produce a firm line of approximation (see Fig. 12). From a theoretical standpoint, as well as from the result of experiments, there is no danger of the formation of aneurism at the point of primary suture for injuries and should not be for secondary suture, as in aneurisms of this class. The vessel should be exposed above and below the aneurism, and temporary hæmostasis obtained by a very mild compression forceps. The aneurismal sac should then be freely opened and dissected down to the position of the opening in the artery. The edges of the opening should be freshened and closed, the same technique being observed as in primary suture.

In the fourth class of cases, *i.e.*, sacculated, fusiform, and arterio-venous aneurisms, the aneurismal sac should be exposed and dissected down to the position of the healthy coats of the artery (Figs. 13 and 14), where it should be amputated, leaving sufficient of the aneurismal coat and arterial wall to allow a row of sutures involving one-sixteenth of an inch of the margin on either side, so that when the suture is complete the size of the vessel will be below its normal calibre. This lessens the arterial pressure of the vessel at that point and there should follow a union of the walls. Care should be taken not to produce an approximation of arterial surfaces covered with coag-

ulated laminæ. A study of the aneurismal varix (Figs. 13 and 14)[1] shows how the aneurismal sac may be amputated or removed from the opening in the artery and the communicating canal closed by suture; also Warren's case.[2] The same can be said of Ro-

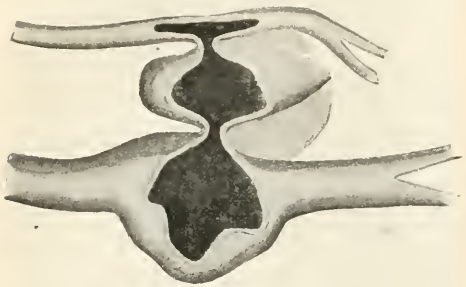

Fig. 13.—Shows Arterio-Venous Aneurism with Small Communicating Canal where Suture could be readily applied (Treves).

land's case.[3] As the longitudinal suture of arteries has been so successful experimentally, little doubt remains but it can be more successful clinically, as asepsis and antisepsis can be more effectually carried out.

Following are reports of two cases in the human subject:

Case I.—Carl A. B——, American, aged thirty-three, married, a salesman; received a bullet wound in the left Scarpa's triangle (22-calibre ball) at two o'clock on the afternoon of October 4th. He was taken to the County Hospital, where I saw him at 6:45 the same evening. The man had profuse hemorrhage from the wound before he was brought to the hospital. There was considerable puffing for four inches below Poupart's ligament; there was no pulsation or bruit in this swelling. The left posterior tibial artery pulsated synchronously with the right and was of the same force and tension. It was believed from these conditions, from the position of the wound, and from the severity of the hemorrhage, that the femoral artery was not injured but that the vein was probably punctured.

Operation: An incision five inches long was made, extending downward from Poupart's ligament parallel with the femoral artery; the internal saphenous vein was exposed and found to be perforated. An opening existed on its anterior and posterior surfaces, the bullet having passed through the middle. These were sutured with a continuous silk suture, No. 8 floss needle. The dissection was continued and the common femoral vein exposed and found injured. The femoral vein had an opening on its anterior surface, three-fourths of an inch above the junction of the profunda, and on

Fig. 14.—Shows Arterio-Venous Aneurism with Large Communicating Canal and No Dilatation of Artery at Point of Communication (Treves' "Surgery")

its posterior surface one-eighth of an inch above the vena profunda femoralis (Fig. 15). It was difficult to control the hemorrhage, as the blood returned through the vena profunda when the clamps were placed upon the femoral vein above and below the wound. It was soon found that the posterior opening could not be exposed without dividing the profunda. A double ligature was placed on the profunda and it was divided between. The posterior surface of the vein was now turned forward and the opening closed with a continuous suture as above. After this was completed the clamps were removed and a little blood escaped from the posterior inferior angle of the wound in the vein; after the insertion of an additional suture in the angle the hemorrhage ceased. The femoral artery had a fragment of tissue torn off the side of its sheath, but the vessel wall was not injured. The bullet was not located. The vein wall was split by the bullet, no part of it being carried away, the usual result of a bullet wound of a vein. There was not a drop of blood escaping from either of the veins when the compresses were finally removed. The field of operation was sponged out with a five-per-cent. solution of carbolic acid, the wound closed, and the leg elevated. No drainage.

The greatest difficulty in the operation was experienced in exposing the posterior surface of the common femoral vein on account of the close relation of the wound to the vena profunda.

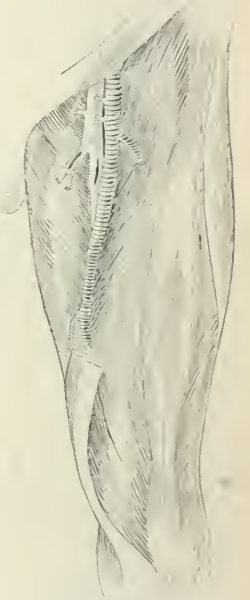

Fig. 15.—Shows Point of Perforation of Internal Saphenous and Femoral Veins.

The patient's temperature began to rise after the operation and on October 8th had reached 104° F. The wound was opened and a gauze drain inserted. The temperature gradually dropped and by October 12th was below 100° F., and remained below 100° F. until November 6th, when it reached 101° F.; November 7th in the morning, 102.2° F. The wound had been suppurating all the time, although the external opening was almost closed. On the morning of November 7th there was considerable hemorrhage, which was believed to be due to suppuration of the sutures in the vein. On November 8th the temperature was 102° F.; pulse, 130; more bleeding. On November 9th the pulse was 144; temperature, 100° F.; patient was coughing and expectorating a bloody mucus. On November 10th I saw the patient for the first time in a week; his temperature was then 101.6° F., and his pulse 104. Examination revealed a large swelling of the upper third of the thigh; the tension of the tumor was very great; blood was oozing from the small opening which still remained, and a dark clot could be seen inside the opening. There was no pulsation in the swelling. It was not auscultated. Patient was anæsthetized, the opening was enlarged, a clot four inches in diameter was shelled out, and in the bottom bright arterial blood flowed per saltum into the wound; digital compression controlled it until the field was entirely cleared. The inner side of the femoral artery for one inch was eroded and had a number of perforations. It was carefully dissected out, about one and one-half inches were resected, a single ligature was placed on the distal

[1] Treves' "Surgery," p. 634.
[2] Boston Medical and Surgical Journal, May 30, 1890.
[3] Bryant's "Surgery," p. 316.

and a double one on the proximal end. The cavity was cleansed and drained. The femoral vein could not be located. Some fragments of the femur which had been broken off by the bullet were removed.

Since November 27th the patient has been doing very well. There has been no disturbance of the circulation of the leg, and the cavity is almost closed. December 8th, there is a very small sinus remaining; patient is in excellent condition. The infection was probably produced by the bullet and the continued suppuration favored by the fragments of bone. January 4, 1897, patient completely recovered; no œdema, and no disturbance of circulation of leg.

Case II.—H. V——, Italian, peddler, aged twenty-nine. He was shot at eleven o'clock September 19th, and was brought to the hospital two hours later.

Clinical history: The patient was shot twice, one bullet passing into the abdominal wall just above the great curvature of the stomach without penetrating the abdomen; the other entered Scarpa's triangle below Poupart's ligament. There was no bruit at this point or increased pulsation noticed at the time the patient was admitted to the hospital. I saw the patient first October 4th; examination revealed a loud bruit, it could be heard with the ear placed six inches from the thigh. There was no tumor and but slight increase in pulsation. The pulsation in the popliteal, dorsalis pedis, and posterior tibial arteries was scarcely perceptible. I examined the case again on October 6th and demonstrated it to a class of students. A thrill could be felt and a bruit could be heard. The latter was the loudest to which I had ever listened. The pulsation though very feeble could now be felt in the dorsalis pedis, but not in the posterior tibial.

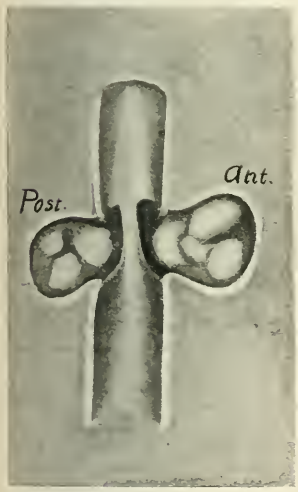

Fig. 16.—Shows Aneurismal Pockets on Anterior and Posterior Surfaces of Femoral Artery. Case II.

Diagnosis: Penetrating wound of the common femoral artery about one and one-half inches below Poupart's ligament. It was decided to cut down and expose the artery, and if a penetrating wound of more than one-half of the circumference was found to make a resection and unite it end to end.

Operation, October 7, 1896. An incision five inches long was made from Poupart's ligament along the course of the femoral artery. The artery was readily exposed about one inch below Poupart's ligament; it was separated from its sheath and a provisional ligature thrown around it but not tied. A careful dissection was then made down along the wall of the vessel to the pulsating clot. The artery was exposed one inch below that point and a ligature thrown around it but not tied; a careful dissection was made upward to the point of the clot. The artery was then closed above and below with gentle compression clamps and was elevated, at which time there was profuse hemorrhage from an opening in the vein. A cavity, about the size of a filbert, was found posterior to the artery communicating with its calibre, the aneurismal pocket. A small aneurismal sac about the same size was found on the anterior surface of the artery over the point of perforation (Fig. 16). The hemorrhage from the vein was very profuse and was controlled by digital compression. It was found that one-eighth of an inch of the arterial wall on the outer side of the opening remained, and on the inner side of the perforation only a band of one-sixteenth of an inch of the adventitia was intact (Fig. 17). The bullet had passed through the centre of the artery, carried away all its wall except the strands described above, and passed downward and backward, making a large hole in the vein in its posterior and external side just above the junction of the vena profunda (Fig. 18). Great difficulty was experienced in controlling the hemorrhage from the vein. After dissecting the vein above and below the point of laceration and placing a temporary ligature on the vena profunda, the hemorrhage was controlled so that the vein could be sutured. At the point of suture the vein was greatly diminished in size, but when the clamps were removed it dilated about one-third the normal diameter, or one-third the diameter of the vein above and below. There was no bleeding from the vein when the clamps were removed. Our attention was then turned to the artery. Two inches of it had been exposed and freed from all

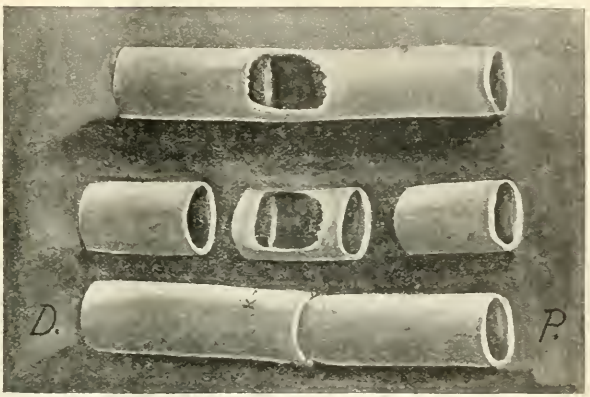

Fig. 17.—Shows Degree of Destruction, Portion Resected, and Appearance after Invagination of Femoral Artery in Case II.

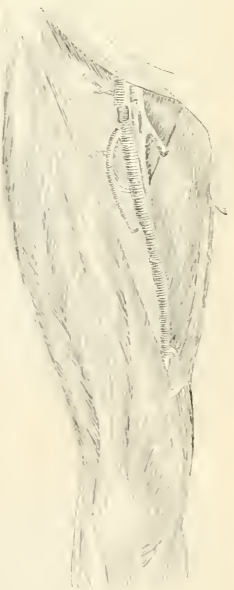

Fig. 18.—Shows Position of Perforation of Femoral Artery and Vein in Case II.

surroundings. The opening in the artery was three-eighths of an inch in length: one-half inch was resected and the proximal end was invaginated into the distal for one-third of an inch with four double-needled threads which penetrated all the walls of the artery, as shown in Fig. 17. The adventitia was peeled off the invaginated portion for a distance of one-third inch; a row of sutures was placed around the edge of the overlapping distal end, the sutures penetrating only the media of the proximal portion; the adventitia was then drawn over the line of union and sutured. The clamps were removed. Not a drop of blood escaped at the line of suture. Pulsation was immediately restored in the artery below the line of approximation, and it could be felt feebly in the posterior tibial and dorsalis pedis. The sheath and connective tissue around the artery were then approximated at the position of suture with catgut, so as to support the wall of the artery. The whole cavity was washed out

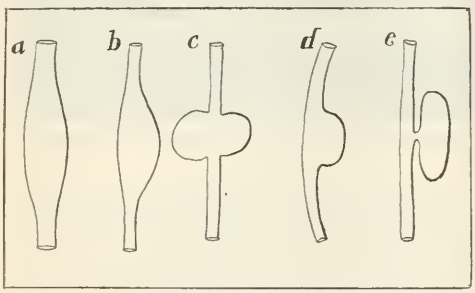

FIG. 15.—Shows Various Forms of Aneurism.

with a five-per-cent. solution of carbolic acid and the edges of the wound were accurately approximated with silkworm-gut sutures. No drainage.

The time for the operation was approximately two and one-half hours, most of that time being consumed in suturing the vein. The artery was easily secured and sutured, and the hemorrhage from it readily controlled. The patient was placed in bed, with the leg elevated and wrapped in cotton.

A pulsation could be felt in the dorsalis pedis on October 11th, four days after the operation. There were no œdema of the leg and no pain. The circulation was good continuously from the time of operation. The wound suppurated; drainage was inserted, but at no time did the patient's temperature exceed 100.8 F. December 8, 1896, the circulation is perfect, the wound has healed with the exception of a small superficial ulcer, one-third of an inch in diameter. The patient has not had an unpleasant symptom since the operation. January 4th, patient is walking about the ward of the hospital, has no œdema and no disturbance of the circulation.

I desire to thank Dr. W. A. Evans for the microscopical work, and Dr. E. H. Lee for assistance in the experiments.

34 WASHINGTON STREET.

Vaccination in Afghanistan.—Miss Lilias Hamilton, who is private physician of the Emir of Afghanistan, has succeeded in convincing her royal patient of the utility of vaccination. Small-pox ravages Afghanistan every spring, killing about one-fifth of the children. The emir has decreed obligatory vaccination in all his States. The order has been given to construct stables and to raise vaccine heifers. Miss Hamilton has been deputed to organize a general vaccination service.—*La Médecine Moderne.*

SULPHO-SALICYLIC ACID AS A REAGENT FOR ALBUMIN IN URINE (THE "SULPHO-TEST").

BY RICHARD STEIN, M.D.,

NEW YORK.

SULPHO-SALICYLIC acid is a white crystalline substance produced by heating salicylic acid with concentrated sulphuric acid. It precipitates all proteid substances. It shows traces of albumin in a dilution of 1–50,000. This reagent was first described by Reoch.[1] Independently of him, MacWilliam[2] described its use, in an exhaustive paper to which I refer those who are interested in details. Ott[3] called attention to it again recently. The reagent was recommended to me by Dr. I. Adler, of this city. I have employed it daily for the last two or three years. As it does not seem to be generally known in this country, a short notice of its excellent qualities as a reagent for albumin for clinical purposes may not be deemed out of place.

MacWilliam employs sulpho-salicylic acid in the form of a saturated solution. I employ it by adding some of the crystals to a small quantity of filtered urine contained in a test-tube. The tube is then shaken. If albumin is present, a white homogeneous precipitate appears instantly. The urine should be acid. Ordinarily, however, it is not necessary to make a preliminary test for the acid or alkaline reaction of the urine. If the urine is alkaline it effervesces after the sulpho-salicylic acid is added. If albumin is present in the smallest traces, a cloudiness appears. When nitric or acetic acid is used for tests, small traces of albumin give rise to stringy, multiform particles suspended in a clear menstruum, the interpretation of which often gives rise to doubt. Sulpho-salicylic acid, however, gives a uniform opalescence which is unmistakable. If albumin is present in greater amount, the precipitate becomes flocculent. The reaction is not interfered with by adding an excess of the chemical. Redissolution of the precipitate never takes place.

As sulpho-salicylic acid precipitates all proteids, inclusive of peptones and propeptones (albumose), it is advisable in every instance to boil the precipitate. If the latter disappears on boiling and reappears on cooling, it shows that it consists of peptones and propeptones (albumose), in contradistinction to the ordinary forms of albumin in urine, viz., serum albumin and serum globulin, which do not redissolve on boiling. By this simple manipulation sulpho-salicylic acid can be used to differentiate between the serines and the peptones.[4] It is important to consider this in pneumonia, for instance, in which peptones are present in large quantities in the third stage. Furthermore, spermatic fluid contains peptones, and thus the first urine passed after the ejaculation of the semen regularly gives a marked precipitate with sulpho-salicylic acid, which disappears on boiling. I have known of candidates for life insurance who were rejected on account of a misinterpretation of this reaction.

Senator[5] has pointed out that propeptonuria may appear as a forerunner of true albuminuria.

The point may be raised, whether it is necessary to employ finer tests than those hitherto used in daily practice. I think that every one will concede that the nitric-acid boiling test is a crude test. It shows only comparatively large amounts of albumin with certainty. In testing for traces with this old test, it is necessary, after boiling the urine and adding a few drops of

[5] Senator. "Die Albuminurie," 2d ed., 1890.

nitric acid, to allow the fluid to cool in order to cause the albumin to precipitate. In addition to this, there is always the danger of redissolving the albumin by an excess of acid. The "sulpho-test" shows a well-marked reaction in instances in which the nitric-acid boiling test fails completely.

Heller's cold test, which consists in carefully pouring a quantity of urine on top of a layer of nitric acid, thus producing a fine white ring at the point of contact of the two fluids, when albumin is present, will always remain an elegant test. It may, however, fail in minimal traces of albumin, or give doubtful results when the urine contains an excess of urates. Admitting its usefulness for most cases, the sulpho-test is the finer test and the more reliable one.

The old test of accidulating the urine with acetic acid and boiling the fluid in the upper part of the tube shows the presence of very small quantities of albumin. A cloudiness appears in the upper boiled part of the fluid which is in marked contrast with the clear fluid in the lower part of the test-tube. According to my experience, the sulpho-test shows the presence of albumin when the acetic-acid boiling test carried out in this way fails.

As to the presence of mucin or nucleo albumin in the urine, sulpho-salicylic acid does not produce opalescence in the presence of those minimal quantities contained in every normal urine. Opalescence appears only when larger quantities of mucin or nucleo-albumin are present, as in catarrhal affections of the genito-urinary tract.[1]

Although the existence of a physiological albuminuria is undoubted, under conditions which cannot be discussed here,[2] the appearance of albumin in the urine will always remain a sign worthy of investigation in every case. In my office practice I am in the habit of examining two specimens from each patient, a morning specimen passed after rising, and an evening specimen passed after the day's work. As in diabetes (with rare exceptions), we thus find most albuminurias "cyclic," *i.e.*, no albumin or only small traces in the morning, larger quantities in the evening. This proves the necessity of examining the evening urine in every instance. Since the adoption of the sulpho-test, I am generally successful in obtaining traces in morning specimens, when all other tests give negative results. The so-called cyclic albuminuria of the authors must be looked upon with grave suspicion.[3] From personal observations I am inclined to class the cyclic albuminuria under the head of acute nephritis of a very mild type. The systematic use of the centrifuge in this connection, will, I think, prove this conclusively. There is hardly any chronic or subchronic organic ailment which is so amenable to successful treatment as this form of nephritis. It may even be claimed that chronic forms of Bright's disease can be prevented by the early discovery and systematic treatment of this form of albuminuria.

As is well known, in the small contracted kidney, with urine of low specific gravity, albumin is often absent, or it may be present in such small quantities that it cannot be detected by any means hitherto employed. In this instance the "sulpho-test" is of great value, giving positive results when all other tests fail. This is all the more important, as in this form of Bright's disease the search for casts is very often fruitless.[4] A minimal trace of albumin may be the means of revealing this most serious condition.

In conclusion I would say the sulpho-test is more accurate than those tests hitherto employed. It is simple, portable, clean, prompt. It can be used for the differentiation of albumin and peptones. It is the most delicate of all tests for albumin (not excluding that with acetic acid and cyanide of potassium). It is worthy to become universally known as an important aid in the diagnosis of diseases of the kidney.

[4] In order to get a sediment which will precipitate casts, in clear urines with low specific gravity, it might be of advantage to add some substance, like uric acid, before centrifuging.

REMARKS ON TYPHOID FEVER.[1]

By ELMER LEE, A.M., M.D., Ph.B.,

CHICAGO,

VICE-PRESIDENT, AMERICAN ACADEMY OF MEDICINE; CHAIRMAN, SECTION ON STATE MEDICINE, AMERICAN MEDICAL ASSOCIATION; CONSULTING PHYSICIAN, CONVENT OF THE SACRED HEART; AUTHOR OF "PREVENTION AND TREATMENT OF ASIATIC CHOLERA."

Typhoid fever is the expression of a group of symptoms which have for their particular determination the lining membrane of the small bowel. The condition that leads to this determination is always one of some general impairment of the system. It may be caused by bacilli or not.

The simple fact that certain forms of bacilli are found associated with the disease is not positive proof that they are the cause of the affection. As in the case of cholera, twenty-four forms of bacilli are found associated with the fæcal discharges. It seems rather assuming for the physician to say that the comma bacillus, which is only one of the twenty-four, is the certain and constant influence which produces cholera; and why might we not, reasoning from analogy, say it is also a problem to determine, whether typhoid fever is produced by one particular kind of germ? However we may decide, all credit and honor to the bacteriologic laboratory and to the earnest workers who are in it.

The practical treatment of typhoid fever, however, does not depend upon experimentation in the bacteriologic laboratory. It was treated just as well before series of experiments were conducted in laboratories, and it has been treated as well since, without regard being paid to the experiments in connection with bacteriologic study.

So it is in the treatment of cholera. The death rate of cholera has averaged fifty per cent., both before bacteriology was instituted and since that time. Notwithstanding that the home of Koch was in Berlin, just a few miles from Hamburg, the fatality at Hamburg from cholera was fifty per cent., the same as in other places and at other epidemics during the century.

The subject of typhoid fever has been one of earnest study by physicians for a great many years. It has now been determined by a long series of experiments upon patients, in both hospital and private practice, that typhoid fever is actually to be cured by the use of water and without the employment of any drugs whatsoever.

The contention is made by Dr. Woodbridge, an earnest investigator and a thoroughly capable clinician, that the practical results of his treatment are due to small doses of guaiacol in combination with other drugs: whereas the real explanation is to be traced to the fact that he gives water. Recently the doctor visited me at my office; he admitted that water alone might be used successfully, but said that so many years had drug remedies been associated with his line of practice he dared not give them up. If he would go a little further and make the experiment, leave out one remedy and then another, it would be

[1] Read by title, at the meeting of the Mississippi Valley Medical Association, St. Paul, September 8, 1896.

found that he could eliminate the entire list. For is it possible to neutralize septic conditions that exist in a tube twenty-five feet long, such as is the alimentary canal, by the Woodbridge or any similar formula?

Septic matter contained in a test tube cannot be made non-septic by any kind or quantity of drug medicament that would be safe to introduce into the human body. If the experiement with a test tube fails in the laboratory under favorable circumstances, how is it possible to disinfect a twisting, ramifying, complex, convoluted bowel, twenty-five feet long? If it were possible, it would be by empiric methods. Practically, it cannot be accomplished. What is the use, then, of talking about giving a drug, whether it be carbolic acid, guaiacol, or some other agent, and expect it to do impossibilities? Why are we deceiving ourselves about this point?

Furthermore, typhoid fever is only a group of symptoms; it is not an entity. Do you ever see two cases alike? The symptoms are always more or less different. In a large proportion of cases you will not see the rose-colored spots on the abdomen, and then again occasionally you will see them. The cases vary. There is no constant, reliable symptomatology to be found in every case.

The physician should treat the body instead of treating the disease. There is no contraindication to the employment of water, but how is it to be used intelligently and scientifically? Baths are excellent, but the internal use of water is still more efficacious. It has been observed in practice that the external use of water and the irrigations of the bowels may be entirely omitted in the treatment of typhoid fever, provided enough water is introduced into the system through the mouth.

How much water shall we use? The normal physiologic requirement of the average human body per day is two quarts. This may vary materially. If the fever is high, more water is needed than if it were comparatively low. The largest quantity ever given one patient, in twenty-four hours, has been three gallons, which was safely borne. Under such treatment the fever subsides during the first week and convalescence is established, although the ultimate recovery of the patient may be protracted. It sometimes requires months under any treatment that may be instituted. But the less harmful the treatment, the quicker the convalescence and ultimate recovery. With few exceptions, I succeed in reducing the fever and having the temperature normal within one week, and bringing about the ultimate recovery of the patient within three or four weeks, sometimes in a shorter period.

Here is the contention which I desire to make. If it is possible to cure disease without the use of drugs given to any considerable extent, is it not a triumph for medicine? The drug method is empiric and expectant, while the hydriatic is rapid and scientific. It happens oftentimes that the medical profession is reproached by the laity, saying that medicine makes practically no progress, while surgery advances with rapid strides. Electricity and steam are discoveries of comparatively recent date, but see how perfect they are. Would the imperfect methods and such confusion as exist in the practice of internal medicine be tolerated in any other allied science?

The confusion which is noticed in the selection of remedies, in the practice of internal medicine, is largely caused by two mistakes. One is that physiology is either forgotten or imperfectly learned; and the other is the overwhelming number of drugs forced upon us, both by the materia medica and by proprietary corporations which keep the medical profession in a state of constant experimentation—in other words, in a position of disappointment and uncertainty.

It was a sad discovery to me, fifteen years ago, to find that all of the prescriptions written for our information in Fothergill, Bartholow, and Watson were practically of very little use in the treatment of typhoid fever. The disappointment was so great that it resolved itself into a resolution of personal inquiry as to whether there was not some sure way of curing typhoid fever. If no other than the empiric drug way had been found, I would have dropped internal medicine and taken up surgery exclusively; but the profession has succeeded in finding a simple, safe, physiologic method by which to treat this disease. Death in my private practice from typhoid fever has not occurred in a good many years, or since the adoption of hydriatic treatment.

As to baths—is it necessary to use the Brandt bath, which is terrifying both to the patient and the friends, and which produces any amount of inconvenience? Is it expedient to resort to any harsh and distressing measures? Sponging is all very well; a tub bath is very good in its way; but cold baths are not absolutely necessary, especially in private practice.

I have recently adopted a sprinkle bath, consisting of a fountain syringe containing water of a temperature below the normal heat of the body, hung on the wall, the chandelier, or the bedpost, and by means of a small sprinkler nozzle fitted to the end of the tubing the patient is sprayed like a bed of flowers in summer time. The water as it goes on the body is allowed to evaporate, not to be wiped off. This is very satisfactory to the practitioner and the patient; besides, the family can have no objections to it, and at the same time it meets all the requirements of a bathing apparatus.

The object of this hydriatic work has been to simplify the method of treating disease, to get down to something that approaches a science. At first it was thought necessary to irrigate the bowels in all cases, and the practice was carried on to the extent of using two irrigations of two and one-half quarts of water each day. Later on it was found one irrigation would do, and afterward that the irrigation could be omitted. While irrigation of the colon may be excluded in many cases, the rule is to employ one irrigation or injection each day. One teaspoonful of elixo, a liquid soap, is dissolved in the water, to render it more cleansing. Also it was determined that bathing could be omitted in the rapid treatment of typhoid fever, if enough pure water be given internally.

The water which is preferable under all circumstances is the purest water, namely, distilled water. The next to it is boiled water; and next to that, such as may be convenient. Organic substance occasionally in water does not necessarily contraindicate its use or interfere with the welfare of the patient. It should be remembered that the gastric juice of the stomach destroys the organic impurities.

If a large quantity of water is admitted into the system, it will reduce the arterial pressure, and thereby materially moderate the action of the heart. It will also assist metabolism, by reason of the action of water upon the tissues, by its power to dissolve dead matter and to convey it to the emunctories, and thus eliminate poisonous elements from the system. Water helps to establish a better blood circulation in the capillaries; it increases the nutrition of the ultimate cells of the entire body by its aid to osmotic transfusion of the serum, which contains the fibrin, albumin, and salts in solution.

Therapeutic fasting is indicated during the acute stage of the fever. The best results are obtained by the omission of all food for the first few days, or until there is genuine hunger, a good and sure test being a piece of dry bread.

A recognition of the laws of physiology is the basis of the treatment which is advocated in these remarks.

Concerning the pathology of typhoid fever, there is much that is indefinite about it. Post-mortem examinations disclose ulcers in the intestinal wall with proliferation of small cells, a diminution in the red blood corpuscles, and alterations in the quality and the quantity of the blood and circulating fluids.

Treatment without drugs was an accidental discovery. It was a great shock when by accident it was proved that quinine could be dispensed with in the treatment of intermittent fever. I did not get over it for some time. By mistake of a nurse, quinine was omitted on a certain occasion, whereas it was supposed that the patient was having it. The patient got well, but the incident of the nurse's mistake was the beginning of the downfall of dependence on drug treatment.

103 State Street.

Progress of Medical Science.

Acanthosis Nigricans. — This is a disease little known hitherto. It is characterized, according to Tenneson and Leredde, by a pigmentation of the whole body; a generalized papillomatosis, which implicates the buccal mucous membrane; a generalized pruritus, which is a symptom not pointed out in the few cases heretofore described; and a pronounced loss of flesh, associated with marked dyspeptic symptoms and with induration of the left lobe of the liver. Darier thinks it well established, especially by the thesis of Couillaud, that the disease points to carcinomatosis. Lesions of the palm present a characteristic papillomatous appearance. In all cases reported, with one exception, there was abdominal carcinomatosis.

The Influence of Intra-Abdominal Pressure upon the Absorption of Peritoneal Effusions.—As the result of an experimental investigation, Hamburger (*Revue de Médecine*, December 10, 1896, p. 1,008) has determined that in animals the resorption of liquid effusions into the abdominal cavity is, up to a certain point, favored by an increase in the intra-abdominal pressure. When, however, the pressure exceeds a certain degree, resorption is impeded rather than hastened, in consequence of interference with the flow of blood through the vessels. These facts, demonstrable physiologically, can be reproduced by means of artificial homogeneous membranes, so that the process is probably dependent upon a simple physical mechanism, and not upon any special vital activity. The results of this investigation are in accord with clinical observation, inasmuch as rapid absorption of large effusions takes place after a portion of the fluid has been removed by puncture.

The Treatment of Retrodisplacements of the Uterus by Shortening the Round Ligaments.—As the result of an elaborate study, based upon an extended clinical experience and a full consideration of the literature of the subject, Edebohls (*American Gynecological and Obstetrical Journal*, December, 1896, p. 671) contends that shortening the round ligaments is the only operation by which the retrodisplaced uterus can be brought into normal and physiologic anteversion, without establishing always pathologic peritoneal adhesions. All other operations for the correction of retroversion depend for their success upon more or less extensive, more or less firm peritoneal adhesions. The operation of shortening the round ligaments is, in capable hands, as safe and as successful as the other operations for the correction of retroversion of the uterus. Shortening the round ligaments is absolutely free from the disturbances and disasters attending pregnancy and parturition following vaginal and ventral fixation of the uterus. It is therefore indicated and should be the operation of choice whenever it will meet the indications as well as or better than either of the other operations named. Shortening the round ligaments is indicated in all uncomplicated cases of retroversion, retroflexion, and excessive mobility of the uterus requiring operative treatment; in extreme and aggravated cases of anteflexion of the uterus; in cases of retroversion of an anteflexed uterus without adhesions; in cases of simple prolapse of the ovaries, when that condition requires treatment; in cases of adherent retrodisplacement of the uterus, with or without adhesions of tubes and ovaries, these organs being in a condition to justify their conservation. The adhesions are first to be broken up by colpotomy, median cœliotomy, or an incision through the peritoneum at the internal ring. Shortening the round ligaments does not compare in efficiency with ventral fixation of the uterus for the correction of uterine prolapse. The operation should always be preceded by curettage of the uterus and is best effected by opening the whole length of the anterior wall of the inguinal canal, drawing the ligament out at the internal ring, and shortening the intra-abdominal portion by stripping back the investing peritoneum, and closing the wound in the manner pursued in the Bassini operation for the radical cure of inguinal hernia, leaving and securing the shortened ligament in its natural situation behind the lower edge of the internal oblique muscle.

The Use of Antitoxin Serum in the Treatment of Diphtheria under the Supervision of the New York City Health Department, with a Résumé of the Published Reports on this Subject. — Drs. Hermann M. Biggs and Arthur R. Guerard (*Medical News*, December 26, 1896), in an exhaustive article on the above subject, conclude by affirming the following facts: 1. That diphtheria antitoxin, when generally employed, has reduced the mortality from diphtheria at least one-half. 2. That it has a distinctly favorable effect on the clinical course of the disease, shortening it and lessening its severity. 3. That the earlier the treatment is commenced, the better the results obtained; the mortality, when adequate doses of antitoxin have been given within the first forty-eight hours of the disease, not exceeding five per cent. 4. That antitoxin is a specific against true diphtheria (*i.e.*, when the symptoms are due solely to the Klebs-Loeffler bacillus) and is less efficacious in mixed infections, but even in these forms of diphtheria is of decided benefit. 5. That it is not necessary to wait for a confirmatory bacteriological diagnosis, but that in every clinically suspicious case of membranous angina, especially in children, a medium dose of antitoxin should immediately be given, and repeated if required by the further developments of the case. 6. That antitoxic serum is a remedy without serious after-effects in the doses which have ordinarily been employed (the after-effects, such as rashes, etc., being insignificant in comparison with the danger of the disease); that it has no injurious action on the kidneys, the heart, or the nervous system; that it does not entirely prevent albuminuria, heart failure, and post-diphtheritic paralysis, because the effects of the diphtheritic toxin which has already entered the system before the administration of the remedy, no matter how soon the treatment is begun, are not always completely counteracted by the antitoxin, though there is every reason to believe that in sufficient doses it does prevent any farther extension of the toxic action after its effects have been produced. 7. That the protection conferred

by immunizing doses of antitoxin is almost absolute for a short period of time, *e.g.*, three or four weeks, when a sufficient number of antitoxin units is administered; and that with a high-grade preparation, when only small quantities of serum are required, the remedy is absolutely harmless, even with the youngest infants. 8. That antitoxin, if not a specific cure for all forms of diphtheria occurring in the human subject, is by far the best remedy for the treatment of the disease. To the critics of the antitoxin treatment, I may repeat the words of a famous German poet, quoted by Professor Soltman:

> "Das ist die richtigste Kritik von der Welt,
> Wenn neben das, was ihm missfällt,
> Einer etwas Eignes und Besseres stellt."

Or, in other words:

> "The best critics in the world are they
> Who, along with that which they gainsay,
> Suggest another and a better way."

The Prognostic Significance of the Diazo Reaction in Typhoid Fever.—As a result of upward of three thousand observations in two hundred and fifty cases of various disorders, Jez (*Wiener medizinische Wochenschrift*, December 19, 1896, p. 2,270) has arrived at the conclusion that the occurrence of the so-called diazo reaction in the urine, especially in cases of typhoid fever, appears to be attributable to toxic substances generated by the typhoid bacillus (typhotoxins) altered in some way in their passage through the human organism. The reaction may appear in the course of a number of diseases and bears no relation to the fever; and it is not dependent upon the form of medicinal or dietetic treatment employed. It appears with considerable constancy in cases of typhoid fever (from the second to the seventh day) and is of a good deal of prognostic significance in this disease, its intensity varying directly with the severity of the morbid process. In cases in which the diagnosis is doubtful, as between typhoid fever on the one hand and gastric fever, acute gastro-enteritis, and malarial fever upon the other hand, the reaction is of differential diagnostic import, inasmuch as it does not appear in the course of any of the three diseases last named. In doubtful cases in which the reaction fails to appear, typhoid fever is to be diagnosticated only with great caution. The occurrence of the reaction in cases of heart disease, nephritis, and tuberculosis must be viewed as a sign of ill omen. On account of its simplicity of application and its great diagnostic and prognostic significance, the test should never be omitted.

Successful Removal of a Cerebellar Tumor from a Child.—At a recent meeting of the Clinical Society of London, Parkin (*British Medical Journal*, December 19, 1896, p. 1,776), reported the case of a child, four years old, who came under observation on account of difficulty in both walking and talking which had been gradually increasing for several months. The child was listless and dull and complained of constant headache. The gait was markedly ataxic, with a tendency to fall backward, and the patient could not raise herself in bed without assistance. The left leg was rigid and both knee jerks were exaggerated. The temperature was subnormal; the pulse was irregular but not slowed. There was no ocular paralysis, but there was intense optic neuritis with hemorrhages, not, however, attended with much loss of vision. The child was treated for a month with large doses of potassium iodide, and during this time had three very severe general convulsions accompanied by marked cyanosis. The condition of the little patient growing gradually worse, the cerebellum was explored. A large scalp flap, with the apex well down on the neck, was raised upward, and after removal of the bone a flap of dura mater with its apex in the opposite direction was turned downward, after ligature of the occipital sinus. A portion of each lateral lobe and the posterior part of the middle lobe were removed, these parts being obviously of a different color than the rest of the cerebellum. Subsequent examination indicated that the tumor was of gliomatous nature. The wound healed rapidly, and in the course of three months the child regained its power of talking distinctly and quickly and was able to walk quite well. The optic neuritis subsided, and there had been no return of any of the symptoms in the subsequent two years and a half.

Acute Spreading Gangrene Successfully Treated with Antistreptococcus Serum. — Steele (*British Medical Journal*, December 19, 1896, p. 176) has reported the case of a girl, a year and a half old, who was accidentally burned on the calf of the left leg with a red-hot poker. The wound was dressed with linseed oil, but would not heal, and the child's health became impaired. In the course of sixteen days a red spot appeared at the centre of the forehead and a small abscess on the left lower eyelid. The lesion upon the forehead increased in size and assumed a gangrenous character, an offensive discharge took place from the nostrils, and profound constitutional symptoms appeared. Ulceration took place at the site of the burn on the leg. The gangrenous portions of the wound on the forehead were cut away and nitric acid was applied with a mop; the ulcers on the eyelid and the leg were curetted and also touched with nitric acid. Improvement failing to take place, these operations were repeated, and again were unattended with permanent good results. The general condition was rather worse than better. At this time, after the lapse of almost a month, five cubic centimetres of antistreptococcus serum were injected beneath the skin and strychnine and brandy administered internally. In the course of a week distinct improvement was noticeable, although suppuration took place in the right elbow-joint, demanding incision and drainage. Perfect recovery ensued ultimately.

The Treatment of Diphtheria with the Antitoxin.—The reports of the results secured with the employment of the antitoxin in the treatment of diphtheria continue favorable. Cuno (*Deutsche medicinische Wochenschrift*, December 24, 1896, p. 483) analyzes 483 cases thus treated at the Children's Hospital at Frankfort on the Main from October 1, 1894, to October 1, 1896. The cases were divided into severe, 282; moderately severe, 112; and mild, 89. Among the whole number there were 51 deaths, 10.5 per cent. Deducting the number of deaths in children brought into the hospital moribund and dying in the first twenty hours, 5, and also those dying of other unrelated disorders long after recovery from the attack of diphtheria had taken place, 12, the mortality was reduced to 7.03 per cent. The reduction in the mortality in the period of antitoxin treatment is made more conspicuous by comparison with the statistics of the previous six years, during which the mortality varied between 32.6 and 43.8 per cent. In the two years considered, the antitoxin alone was used, local applications being eschewed. Full diet was given and heart failure was guarded against by the administration of alcohol and injections of camphor. When albuminuria and nephritis appeared, packs, sweats, and rarely injections of pilocarpine were employed.

The Disintegration of Leucocytes in the Course of Leukæmia and Profound Anæmias.—Two views have been offered in explanation of the increased number of colorless corpuscles in the blood character-

istic of leukæmia. According to the one there occurs diminished disintegration of those cells, while according to the other there is increased production in conjunction also with increased destruction of the colorless cells. Considerable evidence of increased glandular activity has been adduced in cases of leukæmia with augmented production of colorless cells, to confirm which and to demonstrate increased disintegration of leukocytes, Gumprecht (*Deutsches Archiv für klinische Medicin*, B. lvii., H. 5, 6, p. 523) undertook a series of experimental and clinical observations. In concluding the communication embodying his investigation, this author points out that it is generally known that in the majority of cases of leukæmia the excretion of uric acid or alloxur bodies is increased, and that a close relation exists between the degree of cellular disintegration in the body and the amount of uric acid eliminated in the urine. The morphologic characteristics of this degeneration are known for a number of involution and pathologic processes. According to the disintegrating changes in the nucleus, there may be recognized a hyperchromatosis or a hypochromatosis. Gumprecht's investigation showed that free suspended lymphocytes of varied origin degenerate outside of the body, or on exposure to heat, according to the second form, *i.e.*, hypochromatosis. The outline of the nucleus becomes irregular, its structure is lost, and its chromatin slowly disappears. The leucocytes degenerate according to the same type in a number of profound disorders of the blood. Especially in leukæmias, and among them again the acute forms, the abundance of such degenerating cells is peculiar, as the expression of the nuclein disintegration long postulated by chemists. Under these conditions the same morphologic alterations were present in the lymphocytes and myelocytes as in artificially degenerated cells—disappearance of protoplasm, irregularity of contour of the nucleus, loss of its structure, flattening and vacuolation of the nucleus, and especially slowly progressive loss of chromatin. In profound anæmias there occurs frequently, though not constantly, degeneration of leucocytes, at times almost as extensive as in leukæmic blood. Disintegration of leucocytes is wanting or but slight in normal blood, apart from the polynuclear elements, which represent probably the most mature forms of colorless cells.

The Pathology of Aneurism of the Aorta.—In a recent lecture by Dr. A. Fränkel, of Berlin, syphilis was advanced as one of the chief causes of aneurism. In eleven instances out of thirty cases examined, syphilis could be positively proven. Mercurial inunction is therefore the method of treatment advised.

Treatment of Chronic Gouty Affections. — Dr. Murrell (*Lancet*) reports that he has successfully treated the acute manifestations of chronic gouty affections by a local application, which is as follows: Half an ounce of iodide of potassium dissolved in half a pint of rectified spirit (methylated spirit is used in hospital practice); then one ounce of soap liniment is added, and, finally, one-half drachm each of oil of cajuput and oil of cloves. A piece of lint soaked in this mixture is wrapped around the affected part, covered with protective dressing, and kept in place by a bandage. It acts as a powerful counter-irritant, and the inflammation usually subsides in from twelve to twenty-four hours. Dr. Murrell gives, in addition, a drachm of colchicum wine with ten grains of iodide of potassium three times a day. This produces brisk purgation, sometimes accompanied by vomiting, but it speedily cuts short the attack. This treatment is especially indicated in the case of robust, full-bodied men, to whom the loss of a day's work is a serious consideration. In sciatica, lumbago, and rheumatism affecting one joint, the local application of a liniment containing one-half ounce of salicylate of sodium, one-half drachm of cajuput, fifteen minims of oil of eucalyptus, and one-half ounce of soap liniment in six ounces of rectified spirit affords prompt relief.

Entero-Cutaneous Fistula.—Dr. Bonnet reports a case of entero-cutaneous fistula, due to ascarides lumbricoides, in a child of seven years. Intestinal perforation, localized tympanites, abscess, and peri-umbilical fistula, due to the migration of thirty-five ascarides.—*La Médecine Moderne.*

Movable Kidney.—Dr. Cordier (*American Journal of Obstetrics and Gynecology*, October, 1896) deduces the following propositions: 1. A movable kidney often produces a dilated stomach, with all the accompanying symptoms of a disease of the latter. 2. It is a fruitful source of gall stones, by the pedicle producing a partial obstruction of the common duct. 3. The bending of the ureter often gives rise to a hydronephrosis. This in turn is sometimes converted into a pyonephrosis. 4. It may produce death by a complete strangulation, by a torsion of the vessels and ureter. 5. By dragging on the abdominal aorta and kinking of the vena cava, a condition simulating an aneurism of these vessels may be produced. 6. Pain referred to the region of distribution of the spinal nerves is often induced by a movable kidney's disturbance of the abdominal basin. 7. A general nerve exhaustion (neurasthenia) is frequently induced by this condition interfering with digestion, assimilation, and elimination. 8. Nephrorrhaphy is a safe and effective surgical procedure. 9. All cases of movable kidney, if accompanied by symptoms pointing to the kidney as the source, should be operated upon. 10. In summing up the local and remote results of this now often-recognized condition, I think the correctness of the deductions has often been demonstrated by the disappearance of each and every symptom after a restoration and retention of the kidney in its normal position. 11. Symptoms are not to be relied upon in making a diagnosis of movable kidney; the physical examination is the only trustworthy guide.

Hemorrhoids. — Dr. Coston (*Mathews' Medical Quarterly*) prefers the clamp-and-cautery operation over all others for the following reasons: 1. In the operation with ligature you tie up the most sensitive of all nerve ends, and they are sure to resent it by intense pain, which will continue until the stumps slough and the ligatures come away. In the cautery operation you have no such result to contend with; the nerve end is simply cut away and cauterized, and there is nothing left for it to do but cicatrize, and it is left in the best possible condition for this. 2. The ligature may slip and secondary hemorrhage occur; after the clamp and cautery operation there is no danger of secondary hemorrhage. If hemorrhage occurs it does so immediately, and the operator can blame only himself for it. 3. There is no danger of a recurrence. Kelsey, of New York, and Smith, of King's College, London, both support me in this statement, and they have had a vast experience with this operation. It will be admitted by all that recurrences do follow the ligature operation. 4. Convalescence is much more quickly completed, for the reason that it begins at once under the eschar produced by the cautery, and would be completed by the time the ligatures came away should the two operations be used on separate tumors in the same case at the same time. 5. The mortality following the clamp and cautery operation is practically *nil*. 6. The cautery operation requires less care from the physician after the operation. 7. There are no unpleasant sequelæ.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

New York, January 16, 1897.

NEW VASODILATORS.

THE English physiologists and therapeutists have been especially industrious and successful in supplying the profession with drugs which dilate the arteries, and in contributing to our knowledge of their action. The work in this direction of Lauder Brunton, Fraser, Leech, and Hay is well known. In a recent Bradshaw lecture by Dr. J. B. Bradbury, professor of medicine in the University of Cambridge, some new vasodilators are described and their action is discussed. Dr. Bradbury started out to find some vasodilator which had a more permanent effect upon the arterial walls than nitroglycerin and the nitrite of sodium. In looking for this substance, he chose for his investigation the nitrate derivatives of the higher-valent alcohols and their allies. The nitrates of erythrol and mannitol and some of the sugars were examined. The nitrates of sugars were found to have very little effect, and the investigation was, therefore, ultimately directed mainly to the nitrates of erythrol and mannitol. The experiments were made by the perfusion method through excised organs. The method first originated with Ludwig, and is one by which the element of nerve action is eliminated. The kidney of the sheep was the organ specially experimented upon. Blood tracings were also taken of the vessels in rabbits and pulse tracings in man. It was found that both the nitrate of erythrol and that of mannitol had a vaso-dilating effect which began to show itself slowly and lasted for several hours. This effect was less than that produced by nitroglycerin, but was much more prolonged. Tracings were taken showing the effects of the drugs on animals and also on man. When, for example, nitroglycerin is given to the healthy adult man, the arterial dilatation shows itself a minute and a half after the drug is taken. Its effect continues for from three to five minutes, but at the end of ten minutes the pressure has returned to about normal. On the other hand, when erythrol tetranitrate is given, it is twenty minutes before the effect of the drug is manifest, and fifty minutes before it is decidedly shown, while the effect is not lost until after five hours. Very nearly the same result is produced by giving mannitol hexanitrate, it being nearly an hour before the full effect is shown and over five hours before it has worn off. The direct effect of the above compounds upon the heart is very slight. Indirectly, owing to the diminished work consequent on dilatation of the blood-vessels, there is increased rapidity and sometimes palpitation. The effect upon the urinary excretion is practically *nil*. The organic nitrates, as Dr. Bradbury calls them, so far as they have been investigated, are not diuretics, in this respect differing from glycerol trinitrate or nitroglycerin. Erythrol nitrate melts at 61° C. and the mannitol compound at 113° C. Both are slightly soluble in water, but quite soluble in alcohol and ether. When heated with alkalies, they give the nitrite reaction; that is, they liberate iodine from a slightly acidified solution of iodide of potassium. The dose of the solid organic nitrates of erythrol and mannitol is about one grain, though more may be given if it is thought necessary. They may be administered in the form of pills but better in alcoholic solution, and such solutions are stable and not irritating to the stomach.

Dr. Bradbury has, apparently, not used these drugs to any great extent in practice as yet, but he suggests that they will prove of value in headache, dyspnœa, Raynaud's disease, aneurism, Bright's disease, and angina pectoris.

PROFESSIONAL TACT.

WHEN so much is said concerning the requisites for success in practice, one of the main means to the end —that of using tact with the patient—is too frequently left out of consideration. The possession of this in the highest degree is an evidence of genius, although the talent can be very successfully cultivated to the great benefit of both parties concerned. It is so important an element of success that it often takes precedence of sound learning, ripe judgment, and otherwise large attainments. The impression made upon the patient is the main thing, upon which must rest the ultimate chances of a good and paying practice. The doctor, to be a good business man, must practise his profession in a business-like way. He too often forgets that the patient is naturally a very selfish person, and that he takes no more interest in the physician than that which centres on the possibility of being relieved from pain and in being ultimately cured. The doctor is expected to meet him on that basis of understanding, and nothing more. Hence the more directly the medical attendant can make his interest in that direction manifested, the better impression he will leave. Every sick person welcomes the cheerful adviser, but does not bargain for being bored with gossip, undue frivolity, or want of a real appreciation of the patient's actual needs. His own individuality is the only one which is paramount to everything else. The fact that the doctor has a new horse, a charming wife, or a sick child, does not concern the patient one way or the other, so long as the sick one knows that he is to get the right medicine at the right time. If he is not compelled to interrupt the doctor in some personal narrative for some more explicit direction as to dosage or the like, it is eminently well for both parties.

How often is it truthfully said by the patient: "Our doctor is a very nice man, but the only trouble is he tells such prosy stories about himself, his family, his operations, his writings, his hospital, and his horses, that it is difficult to get him to give more than a passing thought to the patient."

On the other hand, the practitioner who gives his whole time to the wants of the suffering one, confines himself to every detail of direction and to nothing more, manifests a dignified earnestness of purpose in all his dealings, and is apparently too much concerned about the patient to think of himself, is the man always in demand and always welcome. He never shows that he is in a hurry, no other patient is more important than the one in hand, no case more interesting to him, and the patient is always proud to believe that no one of all the clientèle is more ill or more important to the careful and painstaking doctor. More can be accomplished oftentimes in a five-minute visit by strict attention to business than in an hour of twaddle, under the mistaken impression that the doctor is expected to make more of a social than a professional visit. Aside from making the impression on the patient of being careful and methodical, the good doctor never runs the risk of having so much spare time on his hands that he has always, during what should be the busier moments of his day, time enough to tell or listen to an idle story. Sometimes the patient may wonder under such circumstances if some other one in waiting does not grudge the time the doctor is uselessly squandering in the vain effort to be entertaining. If his visits are always such lengthy ones, they must necessarily be comparatively few. In any event, the business at hand is very simple—prescribe and go. The polish of a barrel has not so much to do with the bull's eye as directness of aim.

ANOTHER WAY TO CHEAT THE DOCTOR.

A WOMAN living in this city, whose fortune is estimated at considerably over half a million dollars, recently became alarmed about her health and feared that she had Bright's disease. From the ordinary professional point of view, there was nothing to do but to be examined by her family physician, and then, if she had renal trouble, to put herself under his care. But this wasn't the woman's view, for a thorough physical examination, including examination of the urine, would be expensive. She didn't want to die for lack of treatment if she really was ill; and, on the other hand, if she did not need treatment, there was no use in wasting money on an examination. Examination at a dispensary would be free, of course, but then it might not be thorough enough. She might trust the dispensary doctor to treat her if she had Bright's disease, but she would not trust his diagnosis. So this resourceful lady of frugal mind bethought herself of another scheme. She made application for life insurance in large amount, so large, indeed, that the rules of the company called for an examination by two physicians before accepting her as a risk. The two examiners, both experienced and competent men, called at her house by appointment, and subjected her to a most painstaking examination. Not long after she received notice from the company that she had been accepted, and replied that she had changed her mind and would not be insured at present. This is not so bad as the dispensary dodge, for, although the family physician lost a fee, the insurance examiners did get one. There may even be some among our readers who will rejoice over a new use for an insurance company.

TOUT POUR LA FRANCE.

IN a recent lecture upon intubation at the Children's Clinic in Paris, Monsieur Sevestre is reported in *La Médecine Moderne* as having given the students the following history of the discovery of this useful procedure: "Tubage of the larynx is an invention due to Monsieur Bouchut, who did not succeed at the time in convincing his colleagues. Since then, our modern professors being better advised and having learned that our French procedure was giving marvellous results in foreign parts, took up again Bouchut's idea, perfected the instruments, and to-day this method should be employed by all practitioners."

This is not so hard upon O'Dwyer, whose name is left out, as it is upon the newer generation of French students, because no amount of such talk can detract from the honor due and given by the medical world outside of France to the real discoverer of intubation as it exists to-day. It is the student who will have to unlearn this false and foolish teaching. Bouchut has been accorded by Americans the credit which is due him—and that is saying much more than could ever be said of his own countrymen. Bouchut, like the prophet, "was not without honor save in his own country." It is not now for Bouchut that these claims are put forth—it is for France.

The Hebrew Sheltering Guardian Society Orphan Asylum.—This institution, which was recently quarantined by the health department and the management disciplined by the State board of charities after all of the medical officers had resigned, has just issued its annual report. Although a document intended for circulation among the laity, it contains an appendix in the form of a medical report by the resident physician, which consists of an unjust criticism of the former medical officers, the discussion of an alleged method of curing ringworm of the scalp, and a lengthy article on gonorrhœal vulvo-vaginitis unfit for general distribution. Such report being published by the managers without the knowledge or consent of the medical board, the members of the latter felt themselves called upon publicly to disclaim all responsibility for its appearance, as mentioned in our news column on the 2d inst. It is difficult to understand how reputable physicians, who presumably direct the medical affairs of such an institution, should unhesitatingly publish the fact that they have been ignored by the managers, and yet meekly submit to such insult by continuing in the service?

News of the Week.

The Yellow-Fever Germ.—The London *Times* prints a dispatch from Montevideo, supplementing the report noticed recently in the MEDICAL RECORD, to the effect that the micro-organism of yellow fever has been discovered. The dispatch states that the discoverer, a young Italian physician named Guiseppe Sanarelli, now director of the Uruguayan National Institute of Experimental Hygiene, was led to undertake his studies after having himself recovered from the disease at Rio de Janeiro. The announcement of the discovery, with a description of the micro-organism found, has been sent to the Royal Academy of Medicine of Rome.

Cholera in England.—The transport ship *Nubia* arrived at Plymouth, England, on January 9th, with several cases of cholera on board, among the British troops as well as the Lascar sailors. Three of the soldiers and two sailors died at sea, and another death occurred the day after the arrival of the vessel. The ship was disinfected and the sick were removed to the hospital ship. On the following day two more of the soldiers were stricken.

The Plague in Bombay.—Dr. Manser, senior physician of the principal hospital in Bombay, died on January 5th, of the bubonic plague. The Indian government at Calcutta has sent Dr. Cleghorn, the director-general of the medical service, to Bombay, to report upon the increase of the plague. The mill operatives and their families are quitting the city, thus adding a quarter of a million of unemployed to the country districts. It is now estimated that three hundred and twenty-five thousand persons have fled from the city as a result of the spread of the bubonic plague, scattering contagion in the villages up the country. The *Times of India* says that owing to the exodus on account of the plague the population of Bombay has been reduced by one-half. The weekly mortality is two hundred per thousand, and more shops are closed than open in the native quarter. Despite the panic, many victims of the plague refuse to accept medical treatment, regarding the disease as a visitation of God. The plague is also reported to be raging with great violence at Kurrachee, one of the chief seaports of India, at the extreme northern end of the west coast at a considerable distance from Bombay.

The Famine in India.—The area of famine covers a very large extent of country inhabited by over ninety million people. In two-thirds of this district the distress is very acute, and almost the entire population in some parts, cultivators and laborers, of high and low caste, are crowding to the relief works. In western China, also, a severe famine is reported, and the distress has now been aggravated by severe floods which have destroyed the rice and other growing crops from which relief was expected.

Obituary Notes.—DR. LORENZO RECCHIA, a well-known surgeon of Naples, died recently at his home in that city. He was fifty years of age. The cause of his death was progressive spinal paralysis.—DR. BENJAMIN F. KETCHUM, of Brattleboro, Vt., died suddenly on January 9th, of an affection of the heart. He was born in Troy, N. Y., on Christmas Day, 1837, and was graduated in medicine from the University of the City of New York in 1860. He served through the civil war as a surgeon, and at its termination settled in Brattleboro, where he practised up to the time of his death.

Pseudo-Hermaphroditism.—This was the term employed by Dr. Sherman, of 26 East Sixty-third Street, in sending out invitations to a limited number of professional men on Sunday last, to see at her house an unusual instance of mingled sex. The subject, about twenty-three years of age, presented many features of interest to those who had the privilege of examining it. A woman in feature, voice, action, instinct, and dress, was found with well-developed penis and testes. The rectal orifice, without external sphincter, presented somewhat the features of a vulva, and high up through an orifice suggestive of a cervix a probe could be passed for about two inches. Through this opening there was a discharge of blood, which had been going on for some days, and which the patient stated occurred regularly each month since the age of fifteen. Urine is passed, as Dr. Sherman has observed, through both channels, partly under control of the will: and, according to the patient's statement, menstrual blood escapes at times by way of the urethra. No distinct uterus or ovaries could be made out. After a more thorough investigation the case will be published in full in the MEDICAL RECORD.

Commitment of the Insane.—It is reported that Commissioner Croft of the department of charities has issued an order that hereafter no insane person is to be committed except upon order of a magistrate. Such a rule is in the main good, but there arise conditions which make it an inhumane and dangerous one, and provision should be made for exceptional instances. A magistrate cannot always be found. Prompt restraint and treatment are often of extreme importance, not only to friends and physicians, but to the patient for his own welfare. Then, too, it necessitates the unjust and often dangerous practice of incarcerating acutely insane persons who come into the hands of the authorities in the night time when no magistrate is available. The commissioners should consider these points, and amend their rule.

Society of Medical Jurisprudence.—At the meeting of January 11th the new law relating to the commitment of the insane was discussed. A committee was appointed to consider the matter, to confer with the Neurological and County Medical Societies, and to report at a subsequent special meeting. Dr. Spitzka contended that the commitment should rest wholly within the province of the legally qualified practitioner without legal service of notice upon patient and friends. A motion to appoint a committee to secure repeal of the new law met with opposition.

Investigating an Operation for Appendicitis.—Complaint was made recently to the coroner's office

that the death of a man at the Roosevelt Hospital a few days ago was the result of an error of the surgeons. The man was drunk when brought to the hospital, and it was claimed that his death was due to his being operated upon immediately, before he had recovered from the intoxication. The coroner who investigated the case, however, was satisfied that it was necessary that the operation should be performed at once, and he found also that it was done after consultation with the man's wife, who gave her consent. He therefore exonerated the hospital authorities from any blame.

The Mortality in Cuba.—Some idea of the terrible loss of life in Cuba may be gathered from an item in the *Heraldo*, of Madrid, which paper, speaking of the death rate and the sickness among the soldiers in Cuba, says that a column of four thousand men sent to the island at the beginning of November numbered only seven hundred at the end of that month. Many other columns show similar losses.

Dr. Edward Kershner, formerly medical inspector in the United States navy, has been appointed by the commissioners of charities as chief of the medical staff of the Randall's Island Hospital. Since severing his connection with the navy Dr. Kershner has been professor of hygiene in the Post-Graduate School of this city.

Statue of the Late Prof. Samuel D. Gross.—A statue of the late Dr. Samuel D. Gross, professor of surgery in Jefferson Medical College from 1856 to 1882, has recently been cast in Paris and is expected to arrive in this country toward the end of the present month. The costs of the statue have been defrayed by contributions from the American Surgical Association, of which Professor Gross was the founder and the first president, the Alumni Association of Jefferson Medical College, and a number of personal and professional friends. Congress has appropriated $1,500 for a pedestal, and the statue is to be placed in the grounds of the Smithsonian Institution near the Army Medical Museum in Washington, D. C. The unveiling will take place on the second day of the triennial congress of American physicians in May next.

Pennsylvania State Sanatorium for the Cure of Tuberculosis.—The board of directors of the Pennsylvania Society for the Prevention of Tuberculosis has secured for the proposed new State sanatorium for the cure of tuberculosis a suitable site near White Haven, in Luzerne County, in close proximity to Glen Summit, and covering an area of nearly six hundred acres. A committee, consisting of Dr. J. M. Anders, Dr. Samuel G. Dixon, Miss Redfield, James L. Stanton, and Dr. S. Solis-Cohen, has been appointed to raise the sum of $15,000 for the erection of the necessary buildings.

Schuylkill County (Pa.) Medical Society.—At the annual meeting of the Schuylkill County Medical Society on January 5th, at Pottsville, Pa., the following officers were elected for the ensuing year: *President*, Dr. A. F. Bronson, of Girardville; *Vice-President*, Dr. H. C. Bowman, of Mahanoy City; *Secretary*, Dr. J. W. Cable, of Tamaqua; *Treasurer*, Dr. David Taggart, of Frackville; *Censor*, Dr. G. H. Halberstadt, of Pottsville. The business meeting was followed by a banquet, at which numerous toasts were proposed and appropriately responded to.

An Autumn Singer.—Philadelphia has added another to the not very long list of medical poets. Under the caption of "An Autumn Singer," Dr. George M. Gould, well known as a forceful and eloquent writer and industrious lexicographer, and not less as a busy and successful practitioner of ophthalmic medicine, has recently published an attractive little volume of sonnets, songs, poems, and other verse, which bears the stamp of noble sentiment and fine poetic spirit. The medical profession may well feel proud to include in its ranks this new devotee of the muse.

Low Death Rate.—The lowest death rate for several years is shown by the State board of health report for November. The number of deaths reported is 7,888 or 14.75 per thousand. Deaths from diphtheria are fewer than during the corresponding period of 1895.

Vital Statistics of Philadelphia.—For the week ending January 2d there occurred in the city of Philadelphia 502 deaths—107 more than in the preceding week and 50 more than in the corresponding week of the previous year. The principal individual causes of death were as follows: Pneumonia, 94; pulmonary tuberculosis, 54; heart disease, 35; diphtheria, 24; convulsions, 21. There were reported to the board of health during the week 106 cases of diphtheria, 43 of typhoid fever, 36 of scarlet fever. According to the report of the health officer there occurred during the year 1896, 23,982 deaths, 12,270 of males and 11,712 of females—186 more than in 1895. The individual causes of the largest number of deaths were: Pneumonia, 2,696; pulmonary tuberculosis, 2,524; heart disease, 1,405; cholera infantum, 1,126.

Navy Department, Bureau of Medicine and Surgery, Washington, D. C. Changes in the medical corps of the United States navy for the week ending January 9, 1897. January 2d.—Passed Assistant Surgeon M. S. Guest detached from the *Massachusetts* January 9th and ordered to the *Vesuvius* January 12th. Passed Assistant Surgeon L. W. Atlee detached from the *Richmond* on relief and ordered to the naval hospital, Philadelphia. Passed Assistant Surgeon W. F. Arnold detached from the *Enterprise* and ordered to the *Richmond*. Passed Assistant Surgeon R. P. Crandall detached from the *St. Mary's* and ordered to the naval hospital, Norfolk. Assistant Surgeon Lewis Morris promoted to passed assistant surgeon from June 27, 1895, and ordered to the *Essex*. January 6th.—Medical Director H. M. Wells retired January 20th. January 8th.—Medical Inspector J. R. Tryon ordered to examination for promotion January 11th. Surgeon G. P. Bradley ordered to examination for promotion, Washington, D. C., January 18th.

Clinical Department.

THE ABORTIVE TREATMENT OF TYPHOID FEVER.

By JOHN ELIOT WOODBRIDGE, M.D.,

CLEVELAND, OHIO.

An article appeared in a recent issue of the Medical Record under the caption "The Woodbridge Treatment of Typhoid Fever," in which the author, after an experience limited to the treatment of four cases (taken without regard to the duration of illness or the condition of the patient) finds fault with the method because it did not cut the disease short.

It is more than probable that none of the patients were reported by physicians who had consulted or corresponded with me, or called me in consultation and followed the advice which I gave at the bedside.

There may be better methods of managing typhoid fever than that which I have (for want of a better name) designated "The Abortive Treatment," but I must protest against the use and criticism, under that definition, of any modification whatever. The absurdity of such a procedure must be apparent to the most casual observer, because, if the statistics prove anything, they show that the results that have been obtained by those observers who have taken pains to master the subject as I understand it and have followed implicitly the advice I have given are better than those that have been obtained by any other method; therefore the teaching should be followed in its most minute detail or not at all; at least the neglect of the slightest detail as given in my book should shield my name from criticism as completely as it would deprive it of any share in the honor should the modification of the treatment accomplish more than the original method.

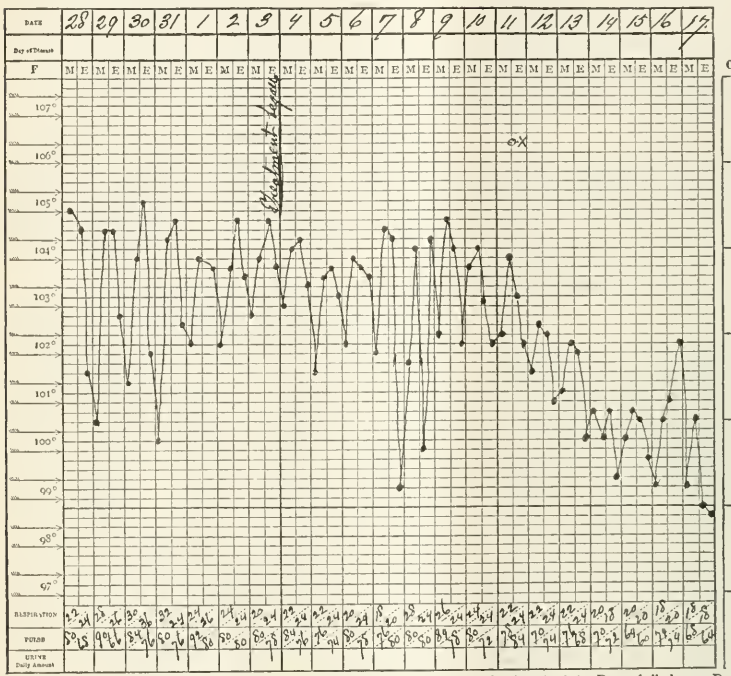

Chart 1.—Bellevue Hospital, Ward 17. Name, John C——. Date of admission, October 28, 1896. Date of discharge, December 7th. Reaction of serum on typhoid bacilli, positive. Diagnosis, typhoid fever. Result, cured in fourteen days. October 28th, alcohol bath if temperature reached 104° F. or over; medication, spirits of nitre. October 29th, alcohol bath if temperature reached 104° F. or over; dilute muriatic acid, twenty minims. Repeated on 30th and 31st. November 1st, alcohol bath if temperature reached 105° F. November 2d, sponge bath if temperature reached 105° F. The nightly record shows that the patient "slept well" throughout the treatment. November 25th, no medication; meat and crackers allowed. Last visit. No baths.

The writer says: "A study of the charts [of the cases] did not show that the usual course of typhoid fever was in any way modified by the treatment instituted. One case, which gave us great hope that a specific had been found, was shown by the serum-diagnosis test of Widal not to have been a case of typhoid fever."

The doctor might have added that a single glance at his patient by an experienced observer showed at once that the treatment had came under the doctor's care sufficiently early in the course of the illness to justify the expectation that the attack could be aborted. None of these patients died, and if the four patients whom I treated in the same division of Bellevue Hospital were fairly representative types of typhoid fever as seen there, the doctor has little occasion to be ashamed of his record, notwithstanding the important fact that he relied upon brief journal articles or excerpts therefrom for his guidance in the application of a most intricate method of treating an infection that has heretofore been regarded as incurable. Had these historical and argumentative papers been considered to be adequate guides for the management of this intractable ailment, my book "Typhoid Fever and its Abortive Treatment" would never have been written. True, before the book was published, more than four thousand cases of typhoid fever had been reported to me as having been treated by the method therein advised, with a death-rate of only 1.42 per cent., but most of these cases not been so applied as to produce the effects that have been so universally accredited to it by who all have used it successfully, viz., prompt alleviation of all of the grave symptoms (some of the doctor's patients were lying with cold coils over distended and tympanitic abdomens after weeks of treatment, and for this reason I advised him to discontinue it). Had these patients been properly treated, as I have directed, not only would the clinical charts have shown the modification of the temperature curve (in some of them at least), but in all of them all tympanites and all abdominal distention and tenderness would have promptly disappeared and the application of the cold coils would not have been necessary; and because these results were not obtained I expressed the opinion that the patient to whom the doctor alludes, in whom he believed he had aborted the disease, did not have typhoid fever.

Herewith are presented the clinical charts of the four cases of typhoid fever which immediately succeeded, in the same division of Bellevue Hospital, the

cases upon which the doctor based his criticism, and which, through the courtesy and under the watchful eye of the visiting physician, were treated by me.

Case I.—C——. This patient had been in the hospital for seven days before he came under my care. He seemed to have pneumonia and was aspirated before I saw him. Besides the ordinary medication, alcohol baths were ordered to reduce the hyperpyrexia.

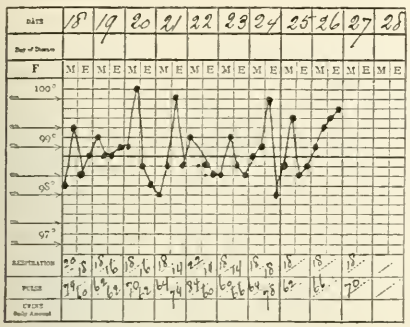

Chart 1.—*Continued.*

The duration of his illness could not be established. After he came under my care on November 3d, he was put upon the abortive treatment of typhoid fever and no other medication or baths were given. On November 25th all medicine was discontinued. He was allowed solid food and I did not think it necessary to see him again, although I visited the hospital daily until after his discharge therefrom, on December 7th.

Case II.—B——. This patient was admitted to the hospital on account of some supposed ailment of the lungs. On October 27th he was aspirated and eight ounces of bloody serum were removed, after which his temperature fell rapidly to normal and was at times subnormal. On November 5th, typhoid fever developed and he came under my care on the 10th of the month. On the 11th he had a slight intestinal hemorrhage. On the evening of the 20th day of the month, the sixteenth day of the disease and the tenth day of treatment, the temperature touched normal, and, although it went up to one hundred afterward, I did not see him after the 25th of the month, when all medication was discontinued and he was allowed solid food. He was discharged on December 3d.

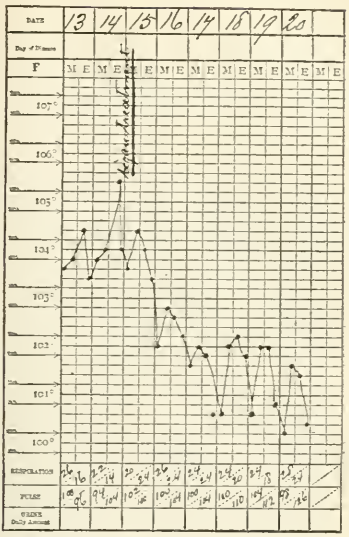

Chart 2.—Bellevue Hospital, Ward 17, 1896. Name, George W. P——. Age, 42. Date of admission, November 13, 1896. Died, November 22d. Reaction of serum on typhoid bacilli, positive. Diagnosis, typhoid fever. Result, died on eighth day.

Had syphilis ten years ago. Had rheumatism thirty years ago, and has been troubled with it ever since; one attack of it lasted six months. Had typhoid fever fifteen years ago. One toe on each foot became gangrenous and had to be amputated. Has been troubled with asthma for the last fifteen years. His feet and legs grow very cold and there seems to be little or no circulation.

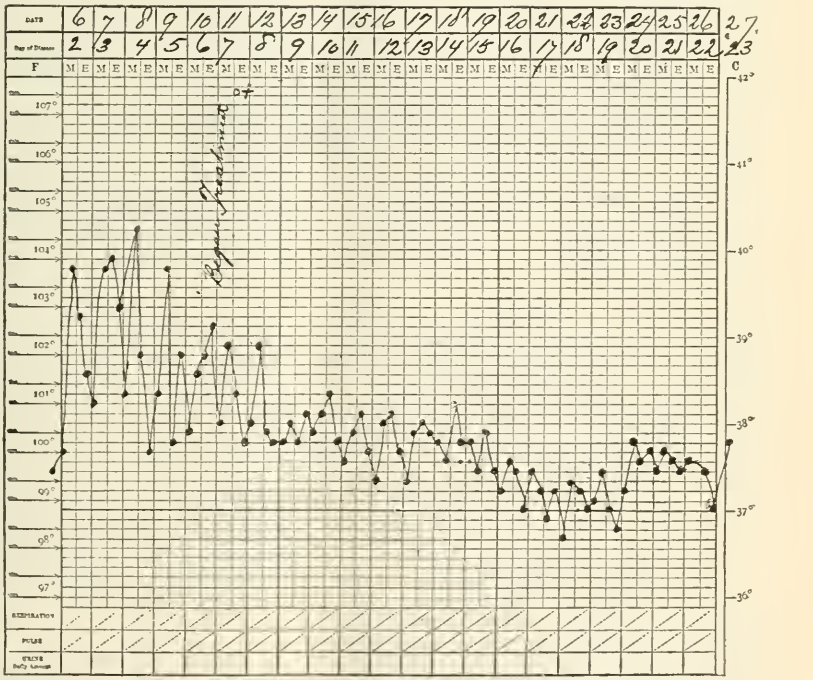

Chart 3.—Bellevue Hospital, Ward 17. Name, Samuel B——. Date of admission, October 27, 1896. Date of discharge, December 3, 1896. Reaction of serum on typhoid bacilli, positive. Diagnosis, typhoid fever. Result, cured in eleven days.

This patient was admitted on October 27th, when the temperature was 104° F. On the 28th it was 105° F. On the 29th he was aspirated and eight ounces of bloody serum were removed. This was no doubt due to some trouble of the lung. His temperature after the operation dropped promptly to normal and was occasionally subnormal. His attack of typhoid fever developed in the hospital on November 1st. Within three or four days after beginning treatment for typhoid fever, all tympanites and abdominal tenderness disappeared. The tongue became quite moist. The patient was free from delirium, and the condition changed rapidly for the better. November 25th, no medication; meat and crackers ordered; last visit. No baths.

Case III.—P——. This patient was admitted to the hospital on November 13th on an outside diagnosis of gastritis (?). He came under my care on the 14th. His history says that he had syphilis ten years ago. He had rheumatism thirty years ago and he has been troubled with it ever since (one attack lasting six months). He had typhoid fever fifteen years ago. He had one toe on each foot amputated, they having become gangrenous. He has been troubled with asthma for the past fifteen years. His feet and lower extremities grow very cold and there seems to be little or no circulation. Present illness: He was so thirsty about two weeks ago that he drank large quantities of cold water and milk, and he had some pain in the region of the stomach which was of a continuous aching character. He went to a physician for relief about a week previous to his admission to the hospital. He has not vomited, but the bowels have been very loose. Eating has no effect upon the pain. He has but little appetite and feels very weak and tired out. He has not been able to sleep much. He has been in bed one week. He came under my care on the 14th and died on November 22d.

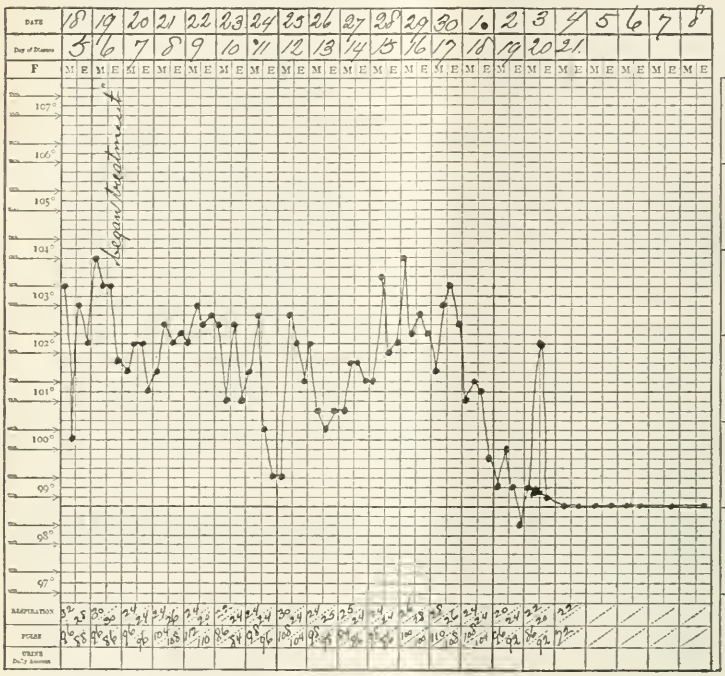

Chart 4.—Bellevue Hospital, Ward 28, November 18, 1896. Name, S——. Sex, female. Date of admission, November 18, 1896. Reaction of serum on typhoid bacilli, positive. Diagnosis, typhoid fever. Result, cured on thirteenth day. November 19th, 2:30 P.M., commenced tablets No. 1 (podophyllin resin, $\frac{1}{200}$ gr.; mercuric chloride, mild, $\frac{1}{16}$ gr.; guaiacol carbonate, $\frac{1}{6}$ gr.; menthol, $\frac{1}{16}$ gr.; eucalyptol, q.s.). November 24th, patient refused to take medicine except at 1 A.M. November 25th, refused medicine both day and night. All tympanites and abdominal tenderness disappeared after the third or fourth day of treatment. The tongue was moist throughout the attack and there was at no time any delirium. No baths. Solid food ordered on December 8th.

Case IV.—S——. This patient came under my care on November 19th. She refused to take the tablets on the 24th and 25th, and would not or could not take the capsules much of the time: hence her attack was unnecessarily prolonged. The evening temperature was subnormal on the thirteenth day of treatment and nineteenth of disease. She was allowed solid food on December 8th, after which I did not see her.

The histories of these cases of typhoid fever cannot be presented as conclusive evidence that the disease can be aborted, but they all presented well-marked clinical signs. The blood of all of them was examined by Dr. Alexander Lambert, bacteriologist of the board of health of New York City, and each gave a positive reaction on the Koch-Eberth bacilli. Each case showed the beneficial effects so often described by many observers, viz., the shortening of the ordinary duration of the disease, moist tongues, absence of delirium, rapid disappearance of all tympanites and abdominal tenderness, and of offensive odor from the stools. As these patients had no baths, and as the diagnosis cannot be questioned, they furnish strong presumptive evidence of the correctness of the diagnoses in the thousands of cases heretofore reported, in which the same treatment produced like effects, and which has led hundreds of observers to use and enthusiastically advocate the abortive treatment of typhoid fever.

Soldiers' Beds.—The soldier's bed varies notably in the different European armies. According to Dr. Viry, the following are the principal varieties, in which, perhaps, we may see the reflection of national characteristics. In England the bed is hard; the soldier lies on a thin mattress that rests on canvas stretched over a frame. In Spain the soldier has only a straw bed, but he is allowed besides this a pillow, two sheets, two blankets, and a covered quilt, sometimes even a cover for the feet. It is almost sybaritic. In Germany and Austria he has a simple straw bed with one or two covers, neither sheet nor mattress. In Russia, until recently, the soldier slept with his clothes on, on a camp bed: but now ordinary beds begin to be used—the result of contact with more civilized countries. After this, it cannot be doubted that the French soldier's bed is the best of all, with its wooden or iron bedstead, a straw bed, a wool mattress, sheets, a brown woollen coverlet, and an extra quilt for cold weather. Thus the bed of the French soldier is the softest of all soldiers' beds, as that of the French peasant is acknowledged also to be the best of all European countries.

Examine before Operation.—Paget says we ought to examine patients for operation with fully as much care as we do for life insurance. If this examination be so conducted, we shall often find that which will make us hesitate and prepare them, before subjecting them to enhanced risk of what may in other respects seem for their good.—Roswell Park.

Therapeutic Hints.

Tuberculosis of the Larynx.—Dr. Solomon Solis Cohen (*New York Medical Journal*, October 24, 1896) says: "Bromoform has been used by me with considerable satisfaction as a local analgesic in cases of painful ulceration of the larynx, especially in tuberculosis: and in several cases of early lesions the application of this agent, followed by the insufflation of iodoform, has been followed by healing. I make no further contention than this, as I have not considered it worth while to experiment with these drugs in cases of long-standing lesions. I desire, however, to call the attention of the fellows to the fact that formic compounds, as in the case of iodoform, chloroform, bromoform, and now formaldehyde, do seem to have, in greater or less degree, a specific antituberculous influence. Whether this be through action upon the bacilli or through restraining influence upon the histologic lesion, I am not prepared to affirm. My impression is that the latter guess is nearer to the truth."

Coryza.—Dr. Thonalla (*Hueckesnagen*) states that acute and chronic coryza, as well as iodinic rhinitis, may be rapidly checked by the introduction into the nasal cavities of suppositories of butter of cacao containing alumnol, oil of valerian, and menthol.

Resorcin for Infantile Diarrhœa.—Dr. Fenwick (*British Medical Journal*) uses resorcin for the following reasons: 1. It is extremely palatable to children. 2. It is devoid of toxic properties, differing in this respect from carbolic acid. (3) It is very inexpensive. 4. Dr. Fenwick finds it highly satisfactory in a large number of cases of intestinal dyspepsia in infants and young children. He gives convincing statistics of one hundred and twenty cases. In chronic cases in which follicular ulceration of the large intestine exists, the drug may be supplemented by such remedies as benzol-naphthol.

Intraperitoneal Rupture of Bladder.—Dr. Heaton (*Boston Medical and Surgical Journal*, September 17, 1896) states that the diagnosis is sometimes one of considerable difficulty, and gives four characteristic symptoms, any one of which may, however, be absent: (1) A history of some form of direct external violence to the hypogastric region when the bladder is distended or moderately full. (2) Sudden violent burning pain in the lower part of the abdomen accompanied by the signs of shock and collapse. (3) A constant or almost constant desire to pass water, with complete inability to do so, or with the passage of only a few drops of blood-stained urine. (4) And if no active treatment be adopted, gradually increasing abdominal distention, with the evidences of free fluid in the peritoneal cavity.

The Calomel Treatment of Typhoid.—Keep the patient in bed until for an entire week the temperature has been normal. Keep him on a sterilized liquid diet as long as he remains in bed. At the beginning of the disease, give ten grains of calomel on alternate days. Give one grain of carbolic acid and three drops of tincture of iodine, every four hours, during the entire illness.—Augustus Elliott.

Washing the Blood.—The mode of procedure may be briefly outlined. Any one of the transfusion apparatuses may be used. My preference is for a blunt-pointed transfusion cannula, connected by three feet of rubber tubing to a large glass funnel. I generally anæsthetize the skin over the vein with chloride-of-ethyl spray, and make an incision about three-quarters an inch long over the vein. This once exposed is incised, the cannula introduced, and a thin silk or gut ligature tied around the vein over the cannula. The water is allowed to run before the cannula is introduced, so as to prevent the entrance of air. I believe that it is best to introduce the saline solution slowly, so, as soon as the fluid begins to enter freely, I lower the funnel as much as is compatible with a pressure barely sufficient to allow the solution to run in. In case these procedures are, for any reason, impossible to be carrried out, the fluid may be introduced within the rectum or under the skin with a large hypodermic syringe. The intravenous method is, however, the most efficient one. The intra-arterial method recommended by Dawbarn may also be tried, but, I believe, has not yet attained any very great degree of popularity. This measure ought to become a routine in all infectious maladies and conditions wherein the blood is charged with toxins which retard elimination, and directly affect the action of the heart and great nerve centres.—Van Schaick, *New York Therapeutic Review*, September.

Furuncle.—During formative period:

℞ Sulphur subl ..... gr. iss.
Pulv. camphor ..... gr. i½.
M. S. Three such capsules or tablets to be given daily.

After evacuation and expulsion of the core the opening is filled with a paste composed of:

℞ Sulphur subl ..... ʒ iiss.
Pulv. camphor ..... ʒ iiss.
Glycerin ..... q.s.
M.

—A. Robin, *El Siglo Med.*

Melancholia.—Ten minims of ether injected deeply into the buttock relieved melancholic attacks upon six different occasions.—Shepherd, *Lancet*, October 21st.

A Tasteless Cup.—A medicine glass has been invented with a partition in the middle, by means of which disagreeable-tasting medicine is separated from some flavored liquid or wine which bathes the lips and mouth before the dose is swallowed.

Dentifrice for Blackened Teeth.—

℞ Pulv. potass. chlorat ..... 14 gm.
Pulv. boracis,
Magnes. calc.,
Calc. carb ..... āā 28 gm.
Essen. menth. pip ..... gtt. x.
M.

—*La Méd. Mod.*

Somatose, of which the formula calls for 88.37 of albumose, 7.46 of salts, and 0.24 of peptone has been experimented with by Dr. Wolf, assistant to Professor Monti, of Vienna. By adding it to cow's milk the latter is rendered more digestible, and it is found to exercise a beneficial influence in the slighter dyspeptic derangements of infants, being well borne by delicate children. It is of equal worth in functional digestive disorders of the second childhood.—*La Méd. Mod.*, October 28, 1896.

Bronchitis in Old Age.—

℞ Ac. benzoic ..... gr. iv.
Ac. tannic ..... gr. ij.
Ft. caps. No. i Four or five times daily.

—*Le Prog. Méd.*

Constipation in Infants.—Give no laxative before the third month and no purgative during the first year. To correct give cow's milk, four parts, and sweetened water, one hundred: rectal lavage by means of the urethral catheter, employing two tablespoonsful of glycerin to one litre of water or two tablespoonfuls of oil with the yolk of an egg mixed with four drachms of water; massage; electricity.—Marfan.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, January 7, 1897.

DANIEL LEWIS, M.D., VICE-PRESIDENT, IN THE CHAIR.

Officers.—The election of officers resulted as follows: For *President*, Dr. E. G. Janeway; *Vice-President*, Dr. Everett Herrick; *Trustees*, Drs. J. D. Bryant and Clement Cleveland; *Member of Committee on Library*, Dr. Charles H. Knight; *Member of Committee on Admissions*, Dr. Thomas E. Satterthwaite.

Annual Reports.—The report of the council stated that all matters connected with the academy were in a favorable condition. The committee on library fund had reported progress, and had expressed the hope that before the next annual meeting the sum of $100,000 would have been raised. This year would signalize the fiftieth anniversary, and arrangements had been made for an appropriate celebration (January 29th). With the report were a number of sub-reports, including those of Dr. Douglas, treasurer of the academy, and of Dr. Cushman, treasurer of the trustees. The library committee reported an increase in the number of books of 2,500; total number of volumes in the library exclusive of duplicates, 35,640. The journals for the year were 680, in various languages. Readers, 6,020, besides many who had not registered, as it was desired all should do. An improved catalogue would be finished the present year. The expenditures had been $5,207, leaving a deficit of $117. The committee asked for an appropriation of $4,500 for the ensuing year, and it was granted. Mr. Browne, librarian, and also his assistant, Miss Smith, received commendation for their able services. The reports of the corresponding secretary, Dr. Starr, of the statistical secretary, Dr. Judson, and of the executive committee of the nurses' bureau were also read. The latter showed that two hundred and sixty nurses had registered or re-registered during the year.

Prevention of the Spread of Contagious Diseases.—DR. H. D. CHAPIN read the paper. The effort at prevention of contagious disease could now be made with greater chances of success since bacteriology had thrown so much light on the causation of disease. After defining the word contagion and mentioning the degrees of contagion, the author spoke of disinfection. Methyl violet was one of the most powerful disinfectants and was not irritating. He had used a spray in the throat of a patient who had recovered from diphtheria, but the germs persisted. He was disposed to attribute their early disappearance after using the spray to the methyl violet employed.

It might be considered a rule that the length of incubation and the duration of infection were in inverse ratio to each other. If the incubation was long, the infection developed early and ceased early. When the incubation was short, the disease as such did not exhibit its infective power so soon, but it remained long.

The prevention of contagion was considered under two heads—what could be attempted by the physician and what could be done by the State. In a private house the patient could be isolated on the top floor. The virus should then be destroyed at its sources according to the nature of the disease, and its dissemination by means of clothing, etc., avoided. Movable objects should be taken from the room. A sheet at the doorway, kept damp, served at least as a danger signal. The nurse should not mingle with the family and should change her clothing before leaving the room. The room should be kept warm enough to allow of ventilation by opening a window a little at the top. This would diminish the risk of reinfection of the patient and infection of attendants. The greatest risk of spreading the contagium existed in tenement houses. The patient should occcupy a cot which, owing to its inexpensiveness, could subsequently be destroyed. Discharges should be collected on clean old cloths, which, after serving the purpose of handkerchiefs, could be burned. The solution of sulphate of zinc and common salt, recommended by the board of health, might be kept standing in the room for disinfection of clothing, cups, spoons, etc., by soaking them in the solution. All cloth taken from the room should be boiled. Pillows and other articles should be taken to the roof and exposed for hours to the air and sunshine. For washing the floor and walls, and also for use in the watercloset, a solution of carbolic acid, 1–20, or of corrosive sublimate, 1–1,000. The walls could be rubbed down with stale bread crumbs, which bacteriologists stated would collect any germs which might be present. It had always seemed to him well to employ sulphur fumigation. The thorough airing which followed its use might account for some of the benefit. The ideal method for disinfection of carpets, etc., was steaming, for which there were private plants in cities.

The healthy children should be removed, if possible, until all danger was over. The author approved of the resolution once adopted by the County Medical Society, calling for the establishing of places of refuge for this purpose. Probably the most powerful factor for the spread of contagion was in the public and parochial schools. The amount of air space per scholar was insufficient, and far below that required by law for tenements. In his opinion a most powerful factor in the schools was the arrangement of the wardrobes. He was glad to see important changes in this and other matters being demanded by the board of health. The use of slates and pencils was discontinued. Lead pencils and penholders were not to be transferred without being disinfected. School articles of children attacked by a contagious disease were to be disinfected or destroyed. Books taken home were to be covered once a month with brown paper. A place for drinking was discontinued, and a pitcher of fresh water placed in each schoolroom, renewed at least twice a day, without interchange of cups. Banisters, etc., should be regularly washed with soda solution. Wardrobes should have plenty of air space and not ventilate into the schoolroom.

Dr. Chapin thought much might be accomplished toward prevention of contagious diseases by the method of medical school inspection about to be introduced through the efforts of Dr. Fowler in his official relation to the board of health. Each medical inspector was to be held responsible for the health of the school which he was to visit. The teacher reported to him at his daily visit cases of children apparently not well, of absentees, etc. He was to examine suspected cases, and visit the house of the sick or absentees when necessary. In short, he was to be held responsible for the existence or extension of contagious diseases in his respective school. He was to report daily to the chief inspector.

DR. GEORGE B. FOWLER, health commissioner, opened the discussion. He explained further the work of the health department in the control of contagious diseases, more especially the reasons for having medical inspectors of schools appointed. It was hoped to get control of those cases of contagious disease now not reported as demanded by the law. It was believed that by this system the mortality from contagious diseases could yet be reduced five per cent., although during the past several years a considerable

reduction had already been effected. In evidence of the reduction he exhibited tables showing the percentages of deaths from contagious diseases in New York each year since 1889; also the percentage of cases of these diseases, and finally the actual number of deaths caused by them. Attention was called to the marked decrease in the actual number of deaths from diphtheria and typhoid fever the last year or two, as well as the decrease in the mortality rate for the number of cases reported.

An Age of Education.—Dr. C. S. Benedict, connected with the health department, said this was an age of education. It certainly had been such to the health department, and it had found it so with the people. The health department was different from what it was five years ago, and the people in tenements were far more willing to receive advice from the sanitary inspectors. So far as concerned the establishing of places of refuge for the healthy, it would be far more practical and efficient to establish more hospitals for those sick with contagious diseases, and take them there. In Boston they did this better than in New York, for they transferred five times as many cases of contagious diseases to hospitals in that city as was done in New York. Places of refuge for the healthy would mean provision for three to six well persons to one sick at home, and it would require a house in each district for each of three contagious diseases at least—measles, scarlet fever, and diphtheria. An accurate knowledge of the work of the board of health was not in possession of a large part of the profession in the city. Its purpose was not to usurp the authority of the physician, but to assist him in protecting the public health.

Dr. Joseph E. Winters thought the movement taken by the health board to prevent the spread of contagious diseases in connection with the public schools a most praiseworthy one. Regarding the statistics presented by one speaker, he reminded his hearers of the fact that contagious diseases and the mortality from them ran in cycles, as it were.

Dr. E. G. Janeway thought it was wise to take the greatest amount of precaution necessary to control contagious diseases rather than the least amount which might possibly suffice. It was best in diphtheria, for instance, to err on the safe side. Quarantine in tenements was one of the most difficult things, yet, if we were ever to hold the disease in check, there must be pretty strict quarantine. Disinfection was also necessary. It was well to ask ourselves whether we took proper precautions against carrying the contagium to families that we visited.

Dr. Rupp thought there was too much tendency in discussing the economic side of these questions to approach it only from the point of view of the rich man, whereas those who were most affected belonged to the very poor. As to the position which the board of health assumed toward the general practitioner, it sometimes did a thing and then notified the attending physician or it did not. When a doctor reported a case of contagious disease he signed his name as well as that of the patient, yet the inspector had been known to demand austerely on calling at the house of the patient, "Who is your doctor?" Inspectors were not always polite to poor people. A good deal of human nature was encountered in the work of educating the public and inspectors. The attending physician was in some way held responsible by the parents for the rudeness of health officers.

Regarding inspection of public schools, he would not minimize the importance of this work, but there was work back of that to be done, which was to improve the homes. The poverty and want of education of the poor were not an affliction to themselves alone. An upholsterer went from the bedside of his children sick with scarlet fever to do some work in the parlor of a mansion. His coat was thrown down upon the floor or a chair, and scarlet fever developed in children, this time not exposed at public schools.

An ordinary school medical inspector was to receive a salary of $30 a month. There was a good deal of difference between a salary of $3,000 for a chief inspector and $300 for the others.

Dr. Fowler said the board of apportionment would not grant a larger sum. Besides, school inspectors gave only an hour or an hour and a half a day, while those receiving a larger salary might be called upon to give their whole time. There was no lack of applicants.

By unanimous consent Dr. Janeway introduced a motion, which was adopted, permitting him to refrain from assuming office until after the anniversary exercises. This was an act of courtesy to Dr. Bryant.

NEW YORK COUNTY MEDICAL ASSOCIATION.

Stated Meeting, December 21, 1896.

Joseph E. Janvrin, M.D., President, in the Chair.

Some Anomalies in Anatomy.—Dr. R. Harcourt Anderson read a paper with this title. A few anomalies which had come under his observation in the dissecting-room, more especially of the muscles of the extremities, were mentioned in the last part of the paper. The remainder dealt with the subject in a more general and more or less theoretical way. Medical students were apt to regard anomalous anatomical conditions coming under their observation in the dissecting-room as curiosities, and any time spent in their study as wasted. In reality their frequency was so common and their importance so great that one should never undertake even a minor surgical operation without bearing in mind the possibility of their presence.

Previous to Charles Darwin most naturalists had believed that species were distinctly created, but several authors were quoted who believed that species became modified. To-day physiological and biological evidence went far to prove that almost all organs of the body were in a state of change, some more than others, and man on the whole was undergoing evolution. A little space was given to the influence of habit or occupation upon the long bones, as the tibia and femur, and upon the muscles. The parts most frequently absent by anomaly were those least needed. The muscles of the hand varied considerably, and anomalies of the limbs were more common than of the trunk. In some instances we saw revival of former types, in others suggestions as to future evolution, and in others fortuitous variations which could not be classified. It had been repeatedly said that mutilations could not be inherited, but he thought Lockwood's experiments with mice conclusively disproved this. Lockwood, by cutting off the tails of mice for many successive generations, finally succeeded in producing a breed without tails. The author thought some of the cardiac murmurs which existed throughout life, and seemed to have little influence upon the health of the individual, might be due to an anomaly rather than to disease. The importance of anomalies of the arteries was mentioned, but its full consideration would require more time than had been allotted him.

Dr. Joseph D. Bryant, on opening the discussion, spoke of the practical aspect of the question, limiting himself to some personal experience. He once ligated,

as he supposed, the brachial artery to arrest hemorrhage in the forearm. It did not succeed so well as was expected and the reason was found to be that bifurcation existed at a point higher than usual. Seven years ago he opened the abdomen to ligate the right common iliac artery for aneurism. Following the usual anatomical guides, he placed a ligature around the artery, but took the precaution which one should always take, to lift up the ligature and test whether the circulation was controlled. To his amazement he found that the circulation was cut off from the left instead of the right common iliac. The ligature was changed to the other artery. The patient died of his disease, and at autopsy the explanation of the fact just mentioned was found to be that the aorta, which as a rule bifurcated at the left of the vertebral column, had bifurcated on the right, and the left common iliac ran across the field where one would expect to find the right. Dr. Bryant had that day operated between attacks in a case of recurrent appendicitis, but careful search proved that this was one of the rare cases in which the appendix was absent. There was a small dimple to indicate where the appendix should have been. There were no evidences of recent inflammatory action. There was an enlarged gland which probably was what had been mistaken for an appendical tumor. Some years ago a patient in Bellevue came under his observation who had before been operated upon by Dr. J. Williston Wright, who had either ligated or removed a part of the facial artery with a portion of a malignant growth of the inferior maxilla. It occurred to the visiting staff of the hospital that it might be well to ligate both external carotids, for at least temporary control of the disease, which had extended. Dr. Bryant performed the operation, and he was congratulating himself on having done the patient some good by relief of pain, etc., when he received word that he had died of secondary hemorrhage. It might be supposed that this was from the external carotid, but it was from the facial, and autopsy showed that in this patient the facial arose from the common carotid—before the bifurcation instead of after.

Dr. W. C. Lusk quoted some experiments which had led the authors to the conclusion that certain infectious diseases in the human race might cause anomalies in the offspring. A glance through the "Index Medicus" showed comparative frequency in the reports of anomalies of monsters, hermaphroditism, and transposition of viscera.

Dr. Gallant said that during four years he spent some time in attending hospital operations for appendicitis, and in only one of many cases did he observe an atrophied or small but otherwise normal appendix. The organ might be found in a great many different positions.

Dr. Manley remarked upon the frequency of variations in position of the abdominal viscera.

Dr. Proben impressed the importance of becoming familiar with palpation of the appendix before operation, which Dr. Edebohls had some time ago proven to be entirely feasible. The position of the appendix post mortem proved little regarding its usual position in life, for it might become accidentally pushed in almost any direction in handling the loose viscera.

Dr. Anderson, in the course of some closing remarks, said enlargement of the thyroid vessels in goitre was not unusual, and he thought much might be accomplished by ligating the larger ones instead of resorting to excision. The position of the appendix depended much upon the weight and size of the viscera, and other conditions. The number of the dead upon whom autopsies were made was too small and limited too closely to the civilized nations to form a basis for positive conclusions regarding some questions of evolution, type, and anomalies. From the practical standpoint, every physician should dissect at least one body a year. In the study of anatomy, textbooks should be referred to only as guides, not as teachers.

Paralysis of the Musculo-Spiral Relieved by Operation.—Dr. John Erdman presented a man who had sustained fracture of the humerus early in September, followed by complete or nearly complete paralysis of the musculo-spiral nerve supplying the forearm. He cut down and relieved the nerve where it was found bound down in fibrous tissue. After ten days response became manifest to faradism and galvanism, and the patient began to use the fingers.

Bag for Sterilized Instruments.—Dr. R. Harcourt Anderson showed a bag, or towel, with slips for holding instruments while being sterilized and during transportation to the patient's house. Rolled up like a towel, it was placed in a clean oiled-silk bag.

Nominations.—For *President*, Drs. Janvrin and Ruggles; *Vice-President*, Drs. F. C. Valentine, J. Blake White: *Recording Secretary*, Drs. McGauran and Porter: *Corresponding and Statistical Secretary*, Drs. N. G. Bozeman and Douglas H. Stewart; *Treasurer*, Drs. J. H. Hinton, S. E. Milliken; *Member of the Executive Committee*, Drs. J. J. Noll, Von Breverhout Thompson, N. J. Hepburn.

Surgical Suggestions.

Notes on the Management of Incurable Cases of Cancer.—Dr. Daniel Lewis (*Medical News*, November 7, 1896) says that the fear of cancer is so depressing that it has been many years since he has used the term in the presence of a patient. When the question is asked, "Is this a cancer?" a truthful description can be given of the nature of the disease without the use of this dreaded designation. We are often led to prescribe tonics in such cases, but hope is the very best one, and will effectually ensure a tranquil nervous system, with all which that condition implies, and it is well, according to Dr. Lewis, never unnecessarily to deprive the patient of its influence. Dr. Lewis says that methylene blue, administered in pills (two to five grains), in combination with arsenic (one-sixtieth grain), has been recommended for cancer of the internal organs, and improvement sometimes follows its use, especially when the disease is in some portion of the alimentary tract. This remedy causes no gastric disturbance, and may be given every six hours for an indefinite period. Dr. Lewis has tested its efficacy in a single case, in which the disease proved to be in the pancreas. For a time there was a mitigation of symptoms. In cancer of the stomach, its action is probably more pronounced, owing to the local effect of the drug. In cancer of the uterus, Dr. Lewis recommends a deodorizing lotion as of the first importance, and one containing eucalyptus is preferable to a plain antiseptic solution. The vagina may also be loosely packed with cotton tampons, saturated with a solution (five per cent.) of aristol in albolene or benzoinol, a dressing which the nurse can readily renew. A vulvar pad of finely prepared oakum is both absorbent, a good deodorizer, and cheaper than cotton, and is equally useful in advanced cases of cancer of the rectum.

Anæsthetics in Adenoid Operations.—Dr. T. Helville Hardie (*Annals of Ophthalmology and Otology*), in the course of an interesting article on adenoid vegetation, gives the following reasons for using anæsthetics: 1. The fact that the operation is usually a painful one. 2. A thorough operation, which is by

most men considered necessary, cannot, as a rule, be performed without general anæsthesia, except in adults. 3. A burned child dreads the fire, and a child that has a curette or forceps used once will ever afterward retain a decided objection to a second introduction of the instrument. Children, like elephants, have long memories of injuries. In the absence of disease of the heart or lungs, when the growth is not limited to one central mass merely, and when the child is old enough to know that it is being hurt and to remember it, anæsthesia should be introduced. Dr. Hardie concludes as follows: 1. Adenoid vegetations should be removed under general anæsthesia in the great majority of young children. 2. The cold snare and cocaine anæsthesia are satisfactory in older children and adults, but cocaine should not be used in young children. 3. Nitrous-oxide anæsthesia is frequently of too brief duration for the proper performance of this operation. 4. Ethyl bromide, apart from the question of its safeness, which is still undecided, is a desirable anæsthetic in many cases. 5. Ethyl bromide is not well taken, as a rule, by very nervous or frightened children. 6. Ether should be substituted for bromide of ethyl when the operation is likely to be a lengthy one. 7. The Gottstein curette is, all things considered, the most satisfactory single instrument, and particularly in bromide-of-ethyl operations.

Peritonitis of Typhoid.—The question of surgical intervention has been studied by Hervieux (*Bul. de l'Acad. de Méd.*, October 27th), and the following conclusions are thought justifiable: 1. In case of typhoid appendicitis and appendicular typhoid peritonitis, the operation is done under the best conditions; it gives the best results, provided the intervention is timely. 2. In case of typhoid peritonitis by perforation, the operation gives some chance of recovery to the patient. The difficulty is to seize upon the opportune moment for intervention. 3. In spite of intestinal ulcerations, suture of the intestine results in cicatrization of the perforation, and the surgical interference has, therefore, good ground.

Pseudo-Actinomycoses are more frequent than generally thought. Dr. Poncet has observed and operated upon such abscess tumors containing yellow grains, and finds twelve instances in literature.—*La France Méd.*, October 30th.

Fractured Clavicle.—When the displacement is great, a splint can be applied direct to the fractured clavicle, in persons who are lean and the bone very prominent, as follows: Take a piece of Hood and Reynolds' dental modelling composition, soften in hot water, flatten it out to a proper thickness, and cut into a strip the length and breadth required, soften again in hot water and dry with a towel; then press or mould it firmly over the clavicle while holding the parts in apposition, exhausting all the air. It acts like a cupping glass; it will stay and not irritate the skin. Apply the sleeve bandage. In children there will be complete union in from twelve to eighteen days; in adults, in from thirty to forty.—Edward Borck.

Vulvo-Vaginitis with hemorrhages in young girls is quickly cured by washing with permanganate solution (1 to 1,000) and cauterizing with silver solution (1 to 50).—Comby.

The Relief of Visceral Tension.—Reginald Harrison's observations would seem to point to the fact that albuminuria is at times due to vascular tension and amenable to surgical measures. The operation of cutting down on the kidney has of late years been rendered comparatively safe, so that in presence of symptoms sufficiently severe to justify the slight risk entailed, no surgeon need hesitate to ascertain for himself whether the condition of the kidney is such as to warrant puncture or limited incision with this object in view. The cases related by Mr. Harrison do not enable us as yet to state with any degree of certainty in what class of cases surgical measures are likely to be attended by benefit to the patient. They merely prove that there are cases in which surgical intervention, undertaken on quite other grounds, has paved the way to immediate and usually permanent recovery. It can obviously only be in cases of nephritis tending to a rapidly fatal issue, or in cases in which the condition of the patient steadily becomes worse, that such radical measures can be justifiable. We do not open the abdomen and scrape the peritoneum because in a few cases laparotomy done for concomitant conditions has determined the retrogression of peritoneal tuberculosis, and physicians may rest assured that cases of nephritis which they have hitherto regarded as peculiarly their own are not yet on the eve of falling wholly into the domain of surgery.—*Medical Press*, October 21st.

Surgical Operations put off until too late are of very frequent occurrence. Operations performed too early are so rare that one never hears of them. The lesson is a very plain one—operate in time if you wish to do all in your power to save your patient. In peritonsillar abscess an aspirating syringe with a long needle will usually find the pus with very little pain, and will often prevent the repeated blind stabbing so annoying to the surgeon and so demoralizing to the patient. Never perform an operation without examining the urine for sugar, no matter what its specific gravity may be. If glycosuria exists, antiseptic precautions should be redoubled, but the condition does not contraindicate necessary surgical interference. Never examine for crepitus in supposed fracture of the skull. Depression or other unevenness of surface, together with symptoms referable to cerebral injury, will enable one usually to make a diagnosis, and will not jeopardize the life of the patient. When fæcal vomiting is one of the indications for surgical measures, a washing out of the stomach should precede the operation. The danger of aspiration of filthy vomited material during or after the anæsthesia is most grave. This accident has cost many a man his life.—*Canada Lancet*, November.

Foreign Body in the Nose, Urethra, etc.—A simple arrangement with which to remove foreign bodies from small passages: A hole is bored in the end of a probe and a thread fastened in it. This is then introduced into the passage and carefully pushed past the foreign body. The string being then held in one hand and the probe in the other, the little whip thus forms a loop, with which the foreign body is easily withdrawn. —Beugnies, *Gaz. Méd. de Liège*, September 10th.

Lembert's Suture is intended to bring into apposition two peritoneal surfaces. It is applied in the following manner to join the two ends of the intestine after excision of a portion of the bowel: A needle carrying a stitch of fine silk is inserted in the long axis of the intestine about one-fourth of an inch from the cut edge and brought out about one-eighth of an inch from the same edge, and then it is passed through the other portion of bowel in the corresponding situation. The stitch should traverse only the peritoneal and muscular coats, and should not involve the mucous membrane. Similar stitches are placed at intervals of about one-sixth of an inch all round the circumference of the bowel. The stitches are then tied and the ends cut short. Thus the cut edges of the intestine are turned inward toward the lumen, and the peritoneal coats are in apposition for about one-eighth of an inch all round the bowel, whereby a rapid union of the peritoneal surfaces is assured.—*Lancet.*

Carcinoma.—Absolute alcohol injected into the tumor at four or five points, and repeated every two or three days for about three months. If an open surface exists, apply as a dressing tannic acid (fifteen to twenty-five per cent.) in alcohol.—H. C. Howard.

Fish Bones can be removed from the throat by giving from four to six ounces of milk, and forty minutes later an emetic dose of sulphate of zinc. The coagulated milk carries the bone out with it.—*General Practitioner.*

Penetrating Wounds of the Abdomen.—It must, however, be admitted that in the absence of serious visceral lesions, penetrating wounds of the abdomen are injuries from which the patients are very likely to recover without operative treatment, and that when such patients are submitted to laparotomy, death may occur solely in consequence of the operation. The general symptoms in cases of penetrating punctured wounds of the abdomen, with the exception of those due to profuse hemorrhage, furnish absolutely no reliable information in the differentiation between simple penetrating wounds and penetrating wounds complicated by visceral injuries. With the exception of the last-mentioned symptom (the escape of the contents of the stomach or intestines through the external wound), and the indication pointing to the necessity of arresting internal hemorrhage, there is nothing about the local or general symptoms in cases of penetrating wounds of the abdomen that enables the surgeon to decide with any degree of positiveness whether visceral injuries exist or not, and consequently whether laparotomy should or should not be performed. Severe shock may attend even a non-penetrating wound, and it may be absent, or at least not well marked, in cases of multiple perforation of the intestines. Vomiting takes place as frequently in wounds of the abdominal parietes and in simple penetrating wounds as when the viscera have been perforated. The pulse is slow and compressible in all cases, and nothing characteristic in its qualities is observed, even if the stomach or intestines have been injured. Pallor is present in all penetrating wounds of the abdomen soon after the receipt of the injury, and it is only more pronounced when produced, at least in part, by sudden and severe internal hemorrhage. Pain is a very unreliable and often misleading symptom, as it may be moderate or almost completely absent soon after the injury has been inflicted, even when multiple perforations are present.—*American Text-Book of Surgery*, p. 677.

The Utility of Omental Flaps in Intestinal Surgery.—Dr. Theodore F. McGraw (*The Physician and Surgeon*, October, 1896) objects to Dr. Senn's advice to use a flap cut from the omentum, or, when that is impracticable, to use completely detached grafts. Dr. McGraw thinks that in order best to accomplish its purpose the omentum should be applied with as little disturbance as possible of its vascular relations. The omentum is normally well supplied with blood-vessels, and probably no small part of its power of resistance to the irritation produced by contact with faeces or pus is due to its great vascular supply. When it is cut into a flap, these conditions are of necessity altered. Some blood-vessels would have to be tied and cut. If, instead of using a flap, we use omental grafts, we have to rely entirely upon their capacity of quick adhesion for their vitality. It is not probable that such grafts, however quickly they might become attached to a raw surface, would long resist the pressure of faeces, if a suture should give away and permit their escape. The detachment of a flap from the omentum and its suture to the bowel would result in a cord-like band, under which the intestine might easily be caught and strangulated. For these reasons, it seems better surgery to apply the uncut omentum wherever possible. It should be drawn over the bowel like a sheet, and its extremity wrapped around the wounded intestine, covering the suture closely and widely. Dr. McGraw is convinced that this gives the best support to the gut, covering the whole abdomen as a sheet, and does not cause danger of intestinal entanglement. When from atrophy or disease the omentum cannot be drawn down to the wounded surface without too much tension, the surgeon may then properly resort to omental flaps or grafts, or use neighboring coils of intestine as splints to the one that is wounded.

Internal Hemorrhoids.—Dr. Dundore (*Mathews' Quarterly*) presents the following conclusions: 1. Ligaturing is the safest method, as there is less likelihood of its being followed by hemorrhage, strictures, or ulcers. 2. The clamp causes less pain and a shorter convalescence, but hemorrhage and stricture of the rectum may very often follow its improper application. 3. Whitehead's method should be limited to those cases in which the entire circumference of the anus is involved. In ordinary cases of one or more hemorrhoids, it should never be used. 4. Simple dilatation of the sphincter, injection of carbolic acid, and Manley's method are simply palliative.

Pyogenic Microbes.—Dr. Bauzet (*Thèse de Paris*) says that microbes are not indispensable to suppuration, which may be caused by filtered or sterilized cultures. Koch's bacillus is pyogenic, and may cause cold or acute abscess, but a cold abscess is not necessarily tuberculosis. The streptococcus is the most common agent in acute septicæmia and pyæmia, and tends to produce most serious acute, diffuse processes for phlegmonous and serous suppurations. It is in most cases the cause of those secondary infections which give peculiar gravity to certain primary general intoxications, as, for instance, scarlet fever. It varies much in vitality and virulence. By the presence of other bacteria it is often made more venomous. The staphylococcus is much more stable. It gives rise to septicæmia or pyæmia of moderate severity, to circumscribed processes in sebaceous glands and cellular or bony tissues. Secondary infection by it is seldom very serious. The pneumococcus may be the cause of suppurations—sometimes very serious—of serous membranes, the pleuræ or meninges, joints or middle ear. Eberth's bacillus is of secondary importance in this relation, but may cause subacute periostitis without superficial lesions. The bacillus coli ranks with the streptococci and staphylococci, and may cause acute general or various forms of local suppuration, urinary, biliary, peri-intestinal suppuration, or salpingitis. But its suppurations are of less acute character, and are less prone to extension or to affect the general system, than those caused by pyogenic micrococci. The gonococcus is not proved to have pyogenetic properties, except as regards the mucosa of the urethra, the conjunctiva, and the female generative organs.

Acute Pelvic Inflammations.—In discussing the question how best to prevent suppuration, Dr. William R. Pryor says, in the *Canada Lancet* for November: "I cannot too strongly urge you to apply to the acutely inflamed pelvis of a woman those general surgical principles which are embodied in the two procedures of (*a*) cutting off the primary source of an infection and (*b*) draining away its results. This is the truest conservatism, for it seeks the conservation of tissue diseased, and, at the same time, protects the general economy against the results of diseased processes. Above all, it leaves the woman her menstrual function. These women are symptomatically and physiologically cured, for they bear babies afterward."

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

CHRISTMAS RECESS—ASSURANCE AGAINST ACCIDENTS FOR DOCTORS—PROFESSIONAL SECRECY—DANGER OF BETRAYING SERVANT TO EMPLOYER—APPENDICITIS IN THE LAW COURTS, IN THE NEWSPAPERS, AND IN THE MEDICAL SOCIETY.

LONDON, December 26, 1896.

CHRISTMAS week scatters students and teachers for the short recess, and most of us spend the holiday in the family circle. In a few days work will begin again. In the mean time, those whose duties require their presence in the hospitals have been as busy as usual, organizing and carrying out plans to make the season as enjoyable as possible to the patients.

The subject of professional secrecy has been kept before the profession ever since the important trial in which it became a universal topic of conversation. A curious case has just been decided in the Scottish court of session. A doctor sued the Northern Accident Assurance Company for compensation for disablement through accidental infection by a wound on his finger in the discharge of his duty. The company declined to pay unless the doctor revealed the name of the patient from whom he contracted the infection. The doctor refused, as that would be to betray a professional secret. He therefore lost his case, as the company would not budge and the judge held that he had not proved his case, although he was to be commended for acting in an honorable manner to his own pecuniary loss.

I fancy the company will not eventually gain by its hardness. Doctors insuring against accidents will need to scrutinize closely the terms of their policies, and select those companies which provide for the contingencies they desire to cover.

Another case that has occurred is an illustration more likely to be repeated. A doctor was sent for and was asked to see and prescribe for a servant and report to the employer the state of her health. The girl was dismissed, and began an action for slander, which was compromised on the advice of the Medical Protection Society, as the doctor's statement was made in the presence of another member of the family. The solicitors suggested that it might be permissible to divulge the matter to the employer, but such a course would be very risky. In the present state of public opinion, a jury would be likely to refuse any excuse for betraying professional confidence. The patient is the party without whose consent the doctor should decline to report on or discuss the case—and that consent ought to be in writing, to prevent all danger of blackmailing.

Appendicitis is in the air. The public has got hold of the word, and people who feel what they used to call "gripes" are anxiously asking their doctors if they are in danger of the new disease. This is the effect of the late trial, which I mentioned in my last letter, during which the word was bandied about in the law courts, and which furnished a glut of copy to the newspapers for more than a week. Some of them discuss the malady with their usual assumption of complete knowledge, though they betray their ignorance in many ways. Most of them suggest that the gain of £75 damages will never compensate the plaintiff for his annoyance and the possible damage to his reputation, for even though he vindicated himself, there are many who will only remember that he was concerned in the case and will not consider who was in the right. It was evidently a case for arbitration, as no jury could be expected, with any amount of evidence, to decide questions of diagnosis or of the progress of a disease; but I hear that notice has been given that a new trial will be applied for.

The scientific aspect of the affection came before the Medical Society at the last meeting, when Mr. Mayo Robson read a paper, detailing six cases associated with general peritonitis in which he had operated during the year; five patients recovered after free lavage and drainage. His operations for appendicitis during the year totalled twenty; nineteen of his patients recovered. He is content to divide them into acute and subacute, instead of adopting the complicated classifications some have proposed. He supported the American surgeons who operate early, as he held that the plan of waiting, too often adopted here, would give fewer successes—it having been proved in all countries that there is little or no risk in removing an appendix before suppuration, perforation, or gangrene has occurred. The operation can be done through a small incision, and by separating rather than dividing the muscular fibres, so as to prevent the subsequent occurrence of hernia. He regards acute onset with rapid pulse and tenderness over the appendix without a tumor as indicating immediate operation. In any stage, a rigor with rise of pulse and temperature indicates septic absorption and calls for operation. With few exceptions it is best to remove the appendix, to prevent it from exciting further attacks. With general peritonitis, he would give the patient a chance in the most extreme case. In such cases he advocated free irrigation with boiled water or weak boric-acid lotion, and free drainage with several large rubber tubes.

One or two surgeons made remarks on the paper, mostly of a congratulatory kind. Indeed, there was no room for criticism. Some preferred sponging to flushing, and the difficulty of obtaining consent to early operation, as well as some other points, was mentioned. As to flushing, Mr. Robson replied that he used it only after sponging the abscess cavity as clean as possible. Then he found flushing more speedy than general sponging.

A MATTER OF INTEREST TO MEDICAL TAXPAYERS.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: At the close of the year and on the threshold of another one, it may perhaps be not without interest to members of the medical profession, both as professional men and as taxpayers, to look at the subject of taxation in relation to the public and private medical charities of this city.

The hearing on the final estimates was held on the 28th of this month, and the writer went down to enter his ineffectual protest against the lavish and almost wicked manner in which the public funds are diverted from their proper uses; and this does not reflect upon the board of estimate and apportionment in any way, for unfortunately many of the grants which are made to private charitable institutions were obtained from the legislature and are mandatory. Some few, however, were within the discretion of the board, and it is to these that I shall ask the attention of the doctors of New York City. The amount which, up to that date (December 28th), had been assigned for public charities for 1897, was $1,240,498 (*City Record*, November 20 and 21, 1896), and for private and State charitable institutions the sum of $1,487,055.32 (*City Record*, November 17, 1896). It will be seen, therefore, that the grant to the private and State institutions exceeds that allowed to the municipal charities by $246,557, pretty close on to a quarter of a million dollars. The list of these private corporations is a long one and includes some which are rather teaching bodies than charitable institutions; as, for example, the New York

Medical College and Hospital for Women, the New York Post-Graduate Medical School and Hospital, the New York Homœopathic Medical College and Hospital, and the New York Polyclinic Medical School and Hospital. In this category also might be included the Sloan Maternity Hospital, as this is under the auspices, and practically under the control, of the College of Physicians and Surgeons. It was represented by the opposition that these are medical institutions with hospital attachments and are not primarily either benevolent or charitable institutions, and but for the medical school there probably never would have been a hospital in existence. This rule holds good with regard to all of them, and notably the New York Post-Graduate Medical School and Hospital, the history of which is familiar to every medical man of this city. This institution asked for $30,000, but was willing to accept almost anything, and a motion was made that the sum of $15,000 be given it for the coming year. In the debate which followed, the school evidently had a friend in the comptroller, who deprecated the dead set that was made against the institution and moved that $25,000 be granted it. At the dinner of the Society of Medical Jurisprudence which was held on December 19th, the mayor, at a speech made at that dinner, spoke brave words in protest against this public looting of the treasury for private purposes, and suggested that it was a proper object for the medical men of the society to take hold of, and certainly there was a feeling of encouragement and hope that, at any rate, the mayor of the city would be found upon the side of opposition against the grant. There was a feeble show of resistance, but, like the famous coon of Davy Crockett, when he found that there was some opposition, he made haste to come down from his tree and voted to grant them the sum of $25,000, within $5,000 of as much as they asked. Had he stood by the corporation counsel and the president of taxes and assessments, $10,000 would have been saved to the city, and it was with a feeling of keen astonishment and disappointment that the opposition was forced to the conclusion that the brave words of the head of the city really meant nothing—that it was after all but a species of post-prandial flatus. Then followed the Homœopathic Medical College and Hospital for $7,500; the Flower Surgical Hospital, so-called, getting $7,500, and the Polyclinic, not being that day represented, got $100, which was increased the next day, however, to $7,500.

Taking it by far and large, it would appear, then, that the grants, certainly to the medical charitable institutions, exceed those of the previous year, for last year the Post-Graduate Medical School got $15,000, now it gets $25,000;[1] the Homœopathic Medical College and Hospital got $6,500, now it gets $7,500; the New York Polyclinic Medical School and Hospital got $100, now it gets $7,500. Members of the medical profession, merely as taxpayers, are interested with all of us in this question, for it would appear that this year, instead of being reduced, the taxes will be materially increased, with apparently no prospect of a reduction if this indiscriminate and abominable manner of giving away the public moneys is indulged in in the future as it has been in the past. We are already face to face with the fact that for this coming year the moneys given away by the trustees of the city exceed the amount which is allowed for the sick poor under the guardianship of the city, and are given to persons who are not really responsible directly to the city, although they may be under some sort of supervision by the State board of charities; but we as medical men know, some of us, alas! by pretty bitter experience, that these same institutions which have their arms elbow deep in the treasury of New York City do, by this indiscriminate system of charity, more harm than good, fostering among their patients a spirit of dependence upon others instead of upon themselves, encouraging a spirit of pauperism, and expecting the doctors to give their time and professional skill gratuitously, which alas! too many of them are fools enough to do for nothing but the empty honor of being connected with this or that medical concern.

There is one other aspect which perhaps it would be well to look at, and it is that this greatest loot of all has occurred under a reform administration from which we certainly had hoped better things. I will frankly admit that in some of these cases the board had no power to act, for the legislation was mandatory, but when it was in their discretion there seemed to be no particular desire to check this extravagant waste. On the contrary, if I may judge from my own observations, with two notable exceptions, the rest of the board were willing to fling the money almost as quickly as it was asked for; indeed, while the question was open as to the Post-Graduate School, these well-dressed and highly bred mendicants kept urging, when the board had finally got up to $20,000: "Oh, make it twenty-five, make it twenty-five!" and when they finally got their plunder there was a buzz of approval and delight, and in one instance a very subdued clapping of the hands. And so it goes on, a disgraceful scramble of greed, plunder, and grab; but where, in God's name, dear brother doctors, does the reform come in?

F. R. Sturgis, M.D.

[1] This does not include $8,000 for its Babies' Hospital.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending January 9, 1897:

	Cases.	Deaths.
Tuberculosis	149	112
Typhoid fever	11	7
Scarlet fever	176	11
Cerebro-spinal meningitis	2	2
Measles	163	8
Diphtheria	287	31
Laryngeal diphtheria (croup)	15	6
Chicken-pox	22	0

Pertussis.—Comby finds the effects of antipyrin absolutely *nil* in this affection, though useful in other spasmodic diseases of infancy.

Cocaine Snuff.—The New York *Sun* (December 30, 1896) prints an editorial under the heading "The Latest New Intoxicant." This new intoxicant consists of cocaine, sugar of milk, magnesia, and menthol or peppermint extract, and is applied to the nostrils as a snuff. Compounded first by a physician as a remedy for catarrh, the patients soon noticed its exhilarating properties, and so its use spread among all classes. In a Connecticut town one poor workman is said to spend as much as $5 a week upon the snuff; even children of tender years and hundreds of factory people have become addicted to its use. An appeal to the legislature is talked of to pass a law to prevent the spread of this evil.

More News from the East.—In addition to the small-pox epidemic at Japanese ports, cholera has revived at Hong-Kong, and though there are not yet many deaths, the plague is increasing and serious results are expected. A severe famine is reported from western China. The inhabitants are dying by scores from starvation.

THE TREATMENT BY SUPERHEATED DRY AIR OF STIFF AND PAINFUL JOINTS, INCLUDING THE RHEUMATIC AND TUBERCULOUS, AT THE HOSPITAL FOR THE RUPTURED AND CRIPPLED.[1]

BY V. P. GIBNEY, M.D.,

NEW YORK.

I HAVE the pleasure this evening of presenting notes of cases selected at the hospital for treatment by means of an apparatus which enables one to employ dry air, heated to a very high temperature, for a period from thirty minutes to one and one-half hours. The value of dry heat in painful joints, whether gouty or rheumatic, whether traumatic or tuberculous, has always been recognized; but it had been difficult to determine just how much heat the skin would stand and how to keep the heat dry enough to make a high degree tolerable.

I have recently had my attention called to this method of treatment, and have used it for the past week or ten days. It has been my aim to treat stiff joints that occurred as a result of tuberculous ostitis of the hip, knee, and ankle, or, in fact, any joints about which tuberculous disease has existed for a sufficiently long time to make one feel sure that no active disease is present.

CASE I.—Firm Fibrous Ankylosis after Tuberculous Ostitis of the Knee.—A boy, ten years of age, was admitted to the hospital in August, 1890, with a knee extensively suppurating, and one that required a partial arthrectomy as an immediate measure of relief. He was discharged in July, 1893, with two sinuses discharging and a range of 15° of motion. His angle of greatest extension was 175°, lacking 5° of being perfectly straight.

He was readmitted in June, 1896, with his knee locked at an angle of 140°—that is, nearly midway between a right angle and a straight line. The sinuses had closed. Under traction, his deformity was overcome by repeated stretchings, frequently with an anæsthetic. For two or three months he has worn no brace, except a perineal crutch.

On November 27th his knee could be extended to 180° and could be flexed to 176°. He was placed in the bath—pulse, 92; temperature, 98.2° F. He remained in the bath forty minutes. The highest temperature reached was 255° F. At this time his pulse was 116; temperature, 99.6° F. On removing his limb from the cylinder, it could be easily flexed to 168°, which was a gain of 4°.

Second bath, November 29th. Temperature, 98.2° F. Time in bath, fifty minutes. Highest temperature, 250° F. A gain in motion of 4°.

November 30th, highest temperature, 260° F. In the bath fifty minutes. Gain of 3° in motion.

December 1st, highest temperature, 262° F. Forty minutes in bath. Gain of 3°.

December 2d, body temperature, 98.8° F. before the bath; immediately after the bath, 100.4° F.; the bath was 260° F. Knee flexed to 158° before, 155° after. Duration, fifty minutes.

December 3d there was a gain of nearly 2° F. in body temperature. The bath itself was 260° F., forty minutes in duration. A gain of 7°.

His seventh bath occurred to-day. Gain of 1° body temperature. Highest temperature in bath, 280° F.

He has worn no apparatus since the treatment was begun, has used the limb, and, while his range of motion has not increased over 20°, the motion is much more easy. He has been free from pain, and there has been no reaction whatever from the use of the limb. His would seem to be an excellent case for very slight motion under an anæsthetic, followed immediately by the use of the bath.

CASE II.—Fibrous Ankylosis in a Tuberculous Knee—No Suppuration.—A boy, seven years of age, admitted June 12, 1896. His disease dates from August, 1895. He has worn a protection apparatus since June. There was, at the time he came under treatment, no sign of abscess. On July 29th it was noted that his leg was perfectly straight, with a small range of motion, say 15°; no signs of active disease. His case was selected as one for experiment, although it was very doubtful whether the active disease was fully arrested. I was desirous of learning the effect upon a knee of this kind. At the date of his first treatment, November 27th, his knee could be moved over a very small arc, 5°. The bath lasted fifty minutes; temperature, 250° F. Without any force there was a gain of about 3° in flexion. His bodily temperature was raised 1.5° F. at the fourth bath, 1° F. at the fifth, and a little less than a degree at the sixth. The highest temperature of any one bath was on this date, and it reached 280° F. There has been a gain of about 12°. No force has been employed, no apparatus used, and, while the knee presents a little fulness, he has had no pain. I am satisfied the joint needs more protection, and the apparatus will be readjusted during the week.

CASE III.—Ankylosis of Deformed Knee, Result of Tuberculous Disease.—Girl, fourteen years of age, was admitted to the hospital in October of the present year, with a history of tuberculous disease extending over a period of six years. She has had two years of bed treatment. At the time of her admission it was impossible to extend the leg beyond 130°. There was no motion allowed at the knee, and any efforts to move the joint elicited great pain. We made an attempt to correct by means of splints, and succeeded in gaining a few degrees, but the treatment was very painful, on one or two occasions requiring an anæsthetic. After two or three baths were given last week in the cylinder, we found that no gain was made in the correction of the deformity and that she was just as sensitive if any attempt at motion was made.

On December 3d, under nitrous oxide, I moved the knee over an arc, say, of 15° or 20°, bringing it into a better position, and at the same time breaking up a number of adhesions. Coming out of the gas, she

[1] Read before and demonstration given to Practitioners' Society, December 4, 1896. I am indebted to Mr. Lewis A. Tallerman, of London, for the opportunity of using the apparatus in the cases here reported.—V. P. G.

complained bitterly of pain, and the knee was at once put into the cylinder; the highest point reached was 280° F. It was fully ten minutes before she got relief. The temperature of the bath on entering was about 180° F. It required 100° F. more to give her the necessary relief. A simple posterior splint was applied on removing the limb. She did not require an anodyne during the night, and her night report was very good. The limb was subjected to another bath this morning, and she is present for your inspection. It may be safely said that the excruciating pain which follows an operation of this kind was lessened by the use of the apparatus. It would have been better to put the limb in at the temperature of 280° F., and then raise the heat to 300° F.

These three cases of tuberculous bone disease in children may be taken as fair samples of the good effects which one may expect from superheated dry air.

The case which I am about to report now, I think illustrates its advantage in convalescent cases of hip disease.

Case IV.—Convalescence in Tuberculous Ostitis of the Hip in an Adult; Joint Free from Deformity, but Quite Stiff and Painful on Use.—A gentleman, twenty-two years of age, was placed under my care by Dr. Robert F. Weir, on November 25, 1887. He was hearty and robust-looking, was an athlete in college, and four years prior to this date he had sprained his hip while playing ball. There was a little stiffness at first, but this soon passed off, and it was a year later before any signs of discomfort appeared. A year later he found it difficult to participate in his exercises, and rest was enjoined. At the time I saw him, he was just recovering from an attempt at correction of deformity and removal of adhesions. A diagnosis of ostitis of the hip was readily made, and he was placed under protection treatment. This has continued to the present time. Abscess has formed, been opened, and finally closed; a second one appeared, and then disappeared. In the last two years I have endeavored to have him go without his apparatus, but whenever he made the attempt pain would be excited, he would rest poorly nights, and he has been quite loath to do away with the traction. He has had the benefit of the best climate, and no pains have been spared to keep his health in excellent condition.

December 3d, he expresses himself after the third bath, now, as very much encouraged. Slept better last night than he has for a long time. The limb can be held much more freely than I have ever seen it. He has not been using his brace since the 30th ultimo. He is bearing his weight on the limb and walking about the floor without any discomfort.

December 4th, at the meeting this evening, he states that he has less dread and apprehension of using his limb. He finds more security when he steps upon it; can lie in bed and swing the left limb around, with leg extended, in a pretty good range without fatigue or pain. The range of motion is increased a little. During the treatment his temperature went up from 98.4° to 101.8° F. His pulse, which was 70 at the beginning, was 96 at the close.

Case V.—Chronic Rheumatic Arthritis Already Improving under Massage and Traction.—A lady, forty-five years of age, came under my care, May 18, 1896. It was in 1890 that her disease began, and the knees were stiff and painful almost from the beginning. She had patronized several of the baths in the United States, with a slight amount of relief, during the earlier years of her disease. It is only fair to state that from July 1, 1896, to November 27th, a vast deal had been accomplished in the way of correcting her deformity at the knees, and in getting some use of her right elbow and of both hands. In addition to massage and traction, she had taken large doses of potassium iodide. From July 29th to October 28th she was in solid plaster-of-Paris bandages, with knees extended to about 155°. When we began treating her with the superheated air, her range of motion was from 130° in flexion to 170° in extension. She has been able for one or two months to use her hands in feeding herself, after a fashion, and even in adjusting her hair; but the thumbs and fingers were so distorted that she was unable to use the third, fourth, and fifth fingers at all, but with the index finger and the thumb she managed to grasp objects. Heretofore, whenever any attempt had been made to move the hands or fingers, rather violent reaction had set in, and it had been necessary to discontinue. She was subjected to this treatment on the 27th. Her temperature was raised 0.2°, her pulse only 5 beats. After this bath we had gained very little, if any, in motion. At present writing she has had four baths, of a temperature ranging from 240° to 260° F. The bodily temperature has been raised less than a degree. She has expressed herself as being very comfortable. Profuse diaphoresis occurs, and for the last two mornings I have employed passive motion of the thumb and fingers, without producing any reaction and very little pain. She winces when I break up little adhesions, but she tells me that the pain soon passes off, and not only her knees are becoming more flexible but her hands as well. There has been very little, if any, gain in the extensibility of the legs. She will probably need breaking up of adhesions under an anæsthetic.

Case VI.—Subacute Arthritis of Knee, Traumatic, with a Small Range of Motion and Pain on Use.—A medical gentleman, twenty-seven years of age, in January, 1893, while skating, fell with knee sharply flexed. From that time up to this present report he has been under the care of Dr. Lewis A. Sayre, who has made use of various appliances; and, in addition to Dr. Sayre's care, the patient has subjected himself to various methods of treatment at the hands of different physicians without obtaining a cure. From time to time he has been nearly well, and would then get a fall or an injury of some kind, which would bring on relapse. At the time he came under this present method of treatment, December 1st, he had a range of motion from 10° to 15°; but beyond this limit the knee pained him a good deal. There were no infiltration, very little tenderness on handling, and no bony enlargement. He was on crutches, wearing a splint, anterior and posterior. He has had four treatments by the hot-air bath, and at the expiration of every treatment he feels much better, is able to use his limb with more ease, and the range of motion is just a little increased. He expresses himself as very much encouraged, because he can use the limb more freely about his room, can bear his weight on it with less pain and distress than heretofore, and it would seem that an excellent result can be obtained.

Case VII.—Chronic Sciatica, with Recurring Acute Attacks, Very Obstinate.—The patient is a man, fifty years of age, who was referred by Dr. John J. Reid for this treatment. He had an attack fourteen years ago, lasting three months. The present attack has lasted four months. The pain is referred down the course of the limb, and he is tender on pressure. He walks as if the limb were deformed, but the range of motion is quite free. He complains a great deal if he stands with the limb or walks with it. He is subjected to the bath this evening, during the meeting of the society, and at the expiration of fifty minutes, temperature 260° F., he expresses himself as feeling much better and able to use the limb more freely. The immediate effect, therefore, is good.

Case VIII.—Traumatic Arthritis without Rheumatism or Gout.—This is a patient seventy years

of age, kindly referred by Dr. Robert F. Weir from his service at the New York Hospital. The history obtained this evening is that he was thrown from a car about a year ago, his left knee being the joint injured. The pain has increased from the time of the injury. The stiffness also has increased. He claims that the treatment by fixation, cautery, and such other applications, that have been made from time to time, have been ineffectual in arresting the progress of the disease. At all events, this evening he is unable to walk, except by assistance. The range of motion is less than 10°. There is considerable tenderness on handling the limb. He is subjected to the bath, at a temperature of a little over 200° F., for fifty minutes; and on removing him from the cylinder, the house surgeon, Dr. Kenerson, moves the limb, and is satisfied that an increase of 15° in motion has been gained.[1]

THE CLINICAL SIGNIFICANCE OF RENAL CASTS.

By GEORGE BARRIE, M.D.,

WASHINGTON, D. C.

The discovery of casts in the urine is a note of warning, the clinical significance of which depends very largely on other conditions existing. The frequency with which these bodies are now met with has changed to a marked degree the medical opinon held some years ago, that a fatal termination could almost invariably be expected whenever this condition was found. The advent of the centrifuge has probably done more to change the earlier view than any other one thing, and has positively demonstrated how much more frequently we are enabled to find casts in the urine by the aid of the powers of concentration of this instrument. I expect to show in my paper:

First, the frequency with which casts and albumin are found in the urine of persons apparently healthy in every respect.

Second, the frequency with which casts and albumin are found in the urine of persons who consult a physician, but who present none of the characteristic symptoms of renal mischief, apart from the presence of albumin and casts.

Third, a few cases with renal insufficiency and all the characteristic symptoms of Bright's disease, under rather unusual conditions.

Fourth, the value of the centrifuge as an aid to diagnosis.

It is not within the province of my paper to enter into or discuss either the anatomy, physiology, histology, or pathology of the renal structure, but rather to attempt to show, from a clinical standpoint, the different groups and classes of cases in which casts are found in the urine, as a result of sedimentation and microscopical examination. It has been my practice, during the past three years, as a matter of routine work, to examine the urine of all patients, independently of what their symptoms might be. The examination of this class of my own cases and the cases of other physicians sent to me, cover in the aggregate several hundred persons who presented none of the objective symptoms of renal disease. As a result of my work and observation in this direction, I have had the belief for some time that casts and albumin are not unusual (in varying proportion) in most diseased conditions of whatever cause; and further, I believed that on investigation it would be found that albumin and casts are present to a less degree in individuals who are apparently in perfect health. I have failed to find any literature bearing on the subject which tells of albumin and casts being found or even looked for in the apparently healthy people who are not very apt to consult the physician.

The difficulty presented itself as to how I might investigate and demonstrate the presence or absence of these bodies in the class supposedly healthy. Through the kindly co-operation and aid of Dr. D. K. Shute, I am enabled to give the results of my examinations of fifty specimens of urine, from the same number of persons of different ages. All of these persons, who are in apparently perfect health, are at present confined in the United States jail.

The results of my examination for albumin and casts are in the aggregate, for these persons who are apparently normal, as follows: In forty per cent. traces of albumin were found, and in twenty-six per cent. casts of the hyaline and granular varieties (and in one case a few of the epithelial variety).

Number of Cases.	Ages.	Casts.	Albumin.
10	15 to 25	5.50 per cent.	5.50 per cent.
10	25 to 35	2.20 "	5.50 "
10	35 to 45	3.30 "	4.40 "
10	45 to 55	1.10 "	3.30 "
10	55 to 65	2.20 "	2.20 "

Hyaline casts, large and small varieties, were found in thirteen cases. Granular casts, small variety, were found in six cases. Epithelial casts were found in one case. Fatty casts were found in no case. Waxy casts were found in no case.

The chemic examination was omitted, for lack of time, for everything but albumin; and as there were absolutely no symptoms of any kind present, it was presumed that the normal excretion of the products of nitrogenous and hydrocarbonaceous waste was going on. It can hardly be considered possible that this number of cases having albumin and casts, but presenting no departure from the normal, is about to develop renal symptoms. That some of them, through neglect or exposure, may become subjects for the hospitals, and a small percentage develop a Bright's disease, with all its characteristic symptoms, is of course possible; but my opinion is that in a majority of the cases, after a time, the casts and albumin will disappear and perhaps reappear, and thus continue to come and go without giving any trouble. I think there is no good reason to doubt that most of us at times pass both albumin and casts in our urine, without it giving rise to any symptoms. When it occurs frequently, it is problematical whether or not the kidneys of such persons are able to withstand shock or strain to any great degree.

My table and results, taken as they are from one institution, and all the subjects occupants of one building, perhaps give some coloring to Fiessenger's[1] theory that Bright's disease is an infectious one. The objection which may be raised—that this class of cases is no criterion on which to base judgment, the vicious lives these individuals lead, their habits of immorality, drinking, exposure, and irregularities of a debauched life favoring this very condition—may be true; still, on the other hand, I think it will be conceded that those in the higher walks and vocations of life become almost as much exposed to this condition, although in an altogether different way. In conducting these examinations, Dr. Shute succeeded in verifying my results. The examinations were made from urine subjected to centrifugal sedimentation, only one microscopical examination being made of each specimen. We frequently hear of cases in which insurance canvassers have persuaded apparently splendid risks into applying for life insurance, when, on urinary examination being made, albumin and casts have been found, much to the

[1] December 7th. Both Dr. Weir and the house surgeon report that the patient is improved, that he is walking about the wards now, that he feels that the treatment has been of benefit and desires its continuance.

consternation of the applicant (who has not complained of any symptoms whatever) and surprise of his family physician, who has never had reason to suspect any trouble. In the next group are considered those persons who consult the physician for some abnormal condition, but who exhibit none of the symptoms of renal mischief, apart from the presence of albumin and casts in the urine. My earlier work in this line with this class of cases averaged twenty per cent. in which albumin was found, varying from a bare trace to one per cent. by weight, in by far the greater number the former condition prevailing. The number in which casts were found averaged eight per cent. These examinations were made of urine taken from persons of either sex and of all ages. The casts found were mostly hyaline in character, large and small, some granular, and in a very few cases a small number of epithelial and fatty. A majority of these cases I have been unable to follow up; in some, however, I have been fortunate enough to secure several specimens at different periods for re-examination, and in these cases have found that the casts disappear and reappear at intervals, the patients in the mean time apparently not suffering in any respect thereby—dietetic, hygienic, and other preventive measures having been advised when the condition was first discovered. Since I have used centrifugal force for the sedimentation of urine, my percentage in the number of specimens in which renal casts are found has greatly increased. By this method of settling, I have been able to find these bodies in about fifteen per cent. of all specimens examined, in persons of all ages, for this class of cases.

Professor Shattuck[2] reports the examination of two hundred and ninety-seven specimens of the urine of as many patients who sought his advice, and who presented no symptoms of renal disease apart from the presence in the urine of albumin and casts. In his table are excluded all cases of fever, and all in which the well-known irritants, bile and sugar, were present, and all cases in which examination rendered it probable that the mechanical effect of crystalline formation in the kidneys was responsible for albumin and casts; also all cases of unquestioned Bright's disease. The following table gives his results:

Number of Cases.	Age.	Per Cent. Albumin and Casts
25	20 to 30	32 per cent.
39	30 to 40	23 "
47	40 to 50	55 "
99	50 to 60	65 "
57	60 to 70	74 "
16	70 to 80	100 "
14	80 to 90	79 "
297		

In a majority of these cases a single microscopical examination only was made. The casts were chiefly hyaline and of the finely granular variety.

I regret being unable to give my results by ages for this class of cases. I will state that my cases embrace subjects from six months old to those who have reached their eightieth year. I have failed to find casts in the urine of some persons of the latter age, but have found albumin in a majority of instances. In infants I have found both.

Dr. Landon Carter Gray[3] reports cases of persistent albuminuria and glycosuria, with frequent hyaline casts, in functional nervous diseases. In none of his cases was there an apparent nephritis present, apart from the presence in the urine of albumin and casts. He also shows from careful examination that these subjects excrete the normal amounts of the terminal products of nitrogenized and hydrocarbonaceous metabolism. He considers the condition simply an attendant symptom of cases of functional nervous disease. He has never seen a case of albuminuria in functional nervous disease pass into well-marked nephritis. In examinations covering thirty-one cases of neurasthenia, heavy traces of albumin were found in thirteen and faint in fourteen; casts were present in almost half of these cases. In five cases of melancholia, albumin was found in all and casts were present in four. In three cases of insomnia, albumin was found in all and casts were present in two. In cases of neuralgia, neuritis, nymphomania, torticollis, tic douloureux, syphilis, alcoholic meningitis, general paresis, and subacute mania, one or more cases of which were examined, albumin and casts were found in a majority of instances.

Brewer,[4] on the other hand, says "that from a single indisposition and malaise, from a slight soreness of the skin to the most torturing neuralgias, from an insignificant and unheeded feeling of depression to the most aggravated cases of melancholia or mania, all these shades and different intensities of mental and nervous disorders may arise from persons with vulnerable kidneys, the demonstrable evidence of disease of these organs being casts alone." He believes that an individual passing urine containing casts, even without albumin, has a damaged constitution. While I believe most of us will readily concur in the opinion that the exhibition of casts in the urine is not a normal condition, it does not seem to me we are justified in making the unqualified statement that such an individual has "a damaged constitution." In those cases in which the functions of the organs are normal, as is ascertained by estimating the amounts of nitrogenous and hydrocarbonaceous waste eliminated, it is hard to see how the kidneys can be damaged to any great extent. It is worthy of notice that in most cases in which the functions of the kidneys are normal, even with the presence of casts in the urine, the epithelial variety is absent, and that in all cases of serious parenchymatous nephritis epithelial casts are abundant.

It seems apparent that in a number of the neuroses (at least as quoted above), in which all the functions of the kidneys are maintained, the presence of albumin and casts in the urine is not of necessity to be looked upon with grave apprehension, although their presence in the urine should excite our suspicion. They are "a note of warning" which it behooves us to heed by adopting the necessary measures for giving the kidneys the rest they require.

There is another class of cases in which all the characteristic symptoms of Bright's disease are present. This type of cases is too familiar to need mention, other than to say that in the cirrhotic form the albumin is usually very slight and at times absent, and the casts are few in number and usually only of the narrow hyaline variety. The output of the end products of nitrogenous waste is always lessened in all forms of recognized Bright's disease, and well-known objective symptoms are usually present.*

Among cases belonging to this last group of recognized Bright's disease, I recall examining a specimen of urine recently of a patient who, twelve years ago, was considered to be in a very bad way. I am informed by physicians who examined his urine at that time and for quite a period afterward, that epithelial and granular and other casts were abundant, the urine was thoroughly impregnated with albumin, and all the pronounced symptoms of a chronic Bright's disease were present. The patient is alive to-day and recently was accepted for life insurance. Ever since the diag-

* I have followed the plan which seems to be generally used, of distinguishing between cases in which albumin and casts are present in the urine without symptoms and cases with the well-known symptoms, objective and subjective, of a characteristic nephritis, applying to the latter form the term Bright's disease. Foster's dictionary gives sixty-two definitions of the term.

nosis was first made, he has lived on a milk diet. The specimen examined by me contained a heavy trace of albumin and abundant hyaline casts: the output of the solids was subnormal.

Another case was that of an elderly gentleman holding an important position in the United States treasury department. He consulted his physician for dyspepsia. An examination I made of the urine revealed a condition that looked serious; the albumin was about two per cent. by weight, and the microscope showed abundance of casts. He died about a month later of uræmia or urinæmia.

In an infant, eight months old, who presented renal symptoms, the urine on examination I found to contain albumin, about one-half per cent. by weight—blood and epithelial and granular casts all persisting for a month and then disappearing. Several examinations have since been made, with negative results.

In a child, twenty-two months old, albumin and casts persisted for three months. Shortly after the disappearance of the albumin and casts the child had an attack of pneumonia, without any recurrence of the kidney lesion.

I have made repeated examinations of the urine of a lady, weighing about one hundred and forty-five pounds, and whose age is thirty-six years. I have been unable to find casts in any of the specimens examined microscopically. The chemic examination sometimes gives a trace of albumin, always slight, the nitrogenous element being always below normal, the daily excretion of urea averaging between two hundred and thirty and two hundred and sixty grains, the quantity of urine passed being always increased. The circulatory and other symptoms of a cirrhotic kidney in its earlier stages are present.

It is this class of cases, of which the last mentioned is a type, that show that examinations made to detect the presence or absence of albumin and casts alone cannot be relied on absolutely. A person may have no casts presnet in the urine and still have the worst form of kidney disease, so that consideration must also be taken of the elimination of the end products of nitrogenous waste and the constitutional symptoms present in renal disease. Since the application of centrifugal force to clinical medicine, the old methods of allowing urine to settle preparatory to microscopical examination is rapidly becoming a thing of the past. By the aid of the centrifuge we can get a concentrated sediment of the urine in from two to three minutes unattainable by the old plan in from twenty-four to forty-eight hours. A specimen of freshly voided urine can be examined microscopically a few minutes after it is passed—the advantages of which cannot be overestimated. It is claimed that all casts are thrown to the bottom of the tube by centrifugal force.

Litten,[5] at the congress of internal medicine held in 1891, read a paper on the clinical use of the centrifuge. He demonstrated the ease with which casts and micro-organisms were sedimented by this instrument in urines which, without its use, gave but feeble or negative results. Its value as an aid to diagnosis and the obtaining of clinical information when the old methods utterly fail is now generally accepted. As Purdy[6] very well puts it: "The centrifuge is destined rapidly to supersede the old method of gravity for all purposes of urinary sedimentation."

What seems to me the most important feature gained by the use of this instrument is that we are able to find out positively any deviation from the normal in the kidney structure, of whatever cause, at a much earlier date than is possible by any other method, and the opportunity it probably gives for aborting some cases that might eventuate into a Bright's disease. In the light of our knowledge at the present day and with the means at our command for discovering any deviation from the normal in the kidney structure, it seems a little surprising that examination of urine of patients is not more general, even though positive symptoms of renal trouble are lacking.

While my table of the first group of cases shows quite a large percentage of persons, apparently healthy, exhibiting both albumin and casts in their urine, I do not think it can safely be regarded as a truly physiological condition; that in most of them the casts will disappear I have no doubt. I do not believe it means more in these cases than a mild bronchitis, with the chances toward a serious result in one condition about equal to those in the other.

In the second group of cases, Shattuck's[2] collection of almost three hundred is very interesting, on account of the very large percentage of the number showing albumin and casts. He has been able to follow a good number of his patients up for several years, and he reports them as being apparently well. The statistics of Dr. Landon Carter Gray[3] also show the seeming frequency and persistency with which they are associated in functional nervous diseases. In my own limited experience with cases belonging to the second group, the percentage in which albumin and casts were found seemed to me quite large: but, from the statistics quoted of Shattuck[2] and Gray,[3] I am compelled to believe more careful examinations might have given even larger results.

That recoveries occur from undoubted Bright's disease is well established, even after it has assumed the chronic form, with perhaps some impairment of the renal functions. Flint[7] considers that we may hope for recovery in not an insignificant number of cases of chronic Bright's disease, and in many cases arrest of further progress. Both Senator[8] and Johnson[9] claim to have seen all symptoms of parenchymatous nephritis disappear after having continued two or three years. We shall have fewer deaths in proportion from Bright's disease in the future, not so much from any therapeutic aid we may expect to get, as from the routine practice that will ultimately be adopted, of examining the urine of all patients, regardless of symptoms. The valuable aid our modern methods of sedimentation give us for microscopical examination, enabling a diagnosis to be made early, is another factor in probably aborting what may become a serious condition. Another means of preventing diseased conditions of the kidneys, I believe, will ultimately be adopted, and that will be the periodical examination of the urine of all persons.

Iodide of Starch in Surgery.—Majewski (*Wiener med. Presse*, No. 19, 1896) advises the use of iodide of starch in suppurating and in neglected wounds, phlegmons, and venereal sores. The mixture of one part of tincture of iodine and two parts of starch is better than iodoform in its action as an antiseptic. It is very hygroscopic, almost odorless, and very agreeable.

THE DIATHETIC ORIGIN OF TISSUE OVERGROWTH IN THE PHARYNX OF THE CHILD.

By HENRY J. MULFORD, M.D.,

BUFFALO, N.Y.,

CLINICAL INSTRUCTOR IN DISEASES OF NOSE AND THROAT, MEDICAL DEPARTMENT, UNIVERSITY OF BUFFALO; LARYNGOLOGIST TO ERIE COUNTY HOSPITAL.

I.—That my position may be clearly understood, let me, in the beginning, outline the purpose of this paper, and also explain its title. By "tissue overgrowth" is meant the condition known commonly as adenoid vegetations; and, further, it is meant, this condition occurring in the child of tender age in whom may be found undeniable signs of inherited diathesis.

It is not the purpose to discuss other causes here. The phase of etiology as suggested by our title alone claims our attention. We understand how syphilis and tuberculosis may give origin to this condition, the part they play in causation being so obvious that it may be granted without debate. But while ready, in the absence of other proven cause, to attribute this origin in our cases, it must have occurred to many observers that these causes are not explanation for every case. This condition is frequently seen in children without other blemish, who are otherwise the picture of health—children without vicious inheritance, whose parents had neither syphilis nor tuberculosis; children the first glance at whom revealed nothing beyond an obstruction to nasal respiration. It is this class of cases which we are to consider; and in discussing their etiology we shall have to mention all possible causes, in order to exclude those not bearing upon our thesis. But, as has been said, this paper is not for the discussion of all causes, our present concern being with this question: Can adenoid vegetations have origin in a diathesis?

I shall reply in the affirmative; and I shall present for consideration an argument, illustrated by proper cases, which supports my answer. The argument carries these propositions: First, that adenoid vegetations do, in certain cases, exist because of a diathesis; second, that this tissue overgrowth is no more than an overgrowth, *i.e.*, normal tissue overgrown its natural limit.

II.—To decide that this tissue is an overgrowth of normal tissue, we must compare its microscopic structure with that of the lining membrane of the pharyngeal vault.

The vault of the pharynx is a part of the body's mucous tract. Its mucous membrane is a protective respiratory one, carrying these distinguishing points: ciliated columnar epithelium; mucous glands and lymphoid tissue in about equal amount, with the lymphoid tissue in certain locations thrown up into tonsil form. If it be true that tonsil tissue has the function of destroying foreign matters carried by the inspired[1] air, this arrangement is most happy. The tonsils are developed where most needed, that is, about the pharyngeal openings leading to the external world and about the openings from the pharynx to other delicate and important organs. This gland arrangement is found about the posterior nares, in the membranes of the vault, and in the membranes covering the posterior surface of the soft palate.[2] The direction of the air current inspired through the nose is inward and downward. It must come in contact, then, after leaving the nose with, first, the tissues of the vault, and later with the tissues lower down. Any harmful micro-organisms coming with the air are caught by the mucous membrane and quickly destroyed by the secretion from these tonsils. About the Eustachian openings in the pharynx the tonsil tissue is well developed. It answers two purposes here: It not only helps to clear the incoming air, but it protects the middle ear from invasion by micro-organisms. This function of protection has been supposed to be held only by the ciliated epithelium;[1] but we must admit that it does not seem quite reasonable to suppose that the ciliary movement is active enough to overcome all micro-organisms. There must be something to destroy, to remove rapidly and without trace, these germs, which are at times of extreme virulence.

In a section of the membrane from a normal pharyngeal vault, prepared for the microscope, we note this arrangement: A first layer of ciliated epithelium; then a layer containing the mucous and lymphoid structures; underneath this the submucosa, a layer made up of connective tissue and elastic-tissue fibres, and carrying the main trunks of the blood and nerve supply of the mucosa.

In a section of adenoid-vegetation tissue, we find precisely the same arrangement, with this difference—the layer carrying the mucous glands and lymphoid tissue is very greatly increased and the blood-vessels in this are in greater number and larger. The minute glands are themselves no larger; they are simply in greater number—a hyperplasia has occurred. The blood-vessels and connective tissue carrying them have increased, for the reason that the tissue supplied by them has increased, and therefore there is greater demand for blood.

We shall say, then, that the adenoid-vegetation growth seems to be an hyperplasia of the constituents of the normal pharyngeal membrane—that it is a simple overgrowth of the normal tissue. It has no function for good, existing as it does in large amount and obstructing passages of great importance to the child. Its presence is doubly a menace; for, besides the obstructive and irritative harm it does, it presents a good field for the growth of micro-organisms. This tissue, closely crowded into a cavity without ventilation, soon becomes the victim of its own secretion. The secretion thickens and becomes foul and irritating. The function of the glands is suppressed and the tissue resistance is lowered. Consequently there may be introduced into the organism, at this point, any disease which depends for its activity upon a germ.

III.—It is now in order to discuss our main proposition: That adenoid vegetations exist in certain cases because of a diathesis.

I believe that this may be true, for I have seen, during the past year or so, a number of cases in which there seemed to be a direct relation between the condition of the vault and a diathesis present in the child. Let me repeat, here, the histories of two of these cases. They are very interesting, and will set forth my meaning clearly. One case is given in complete detail, for it covers the points I wish to make and it is very instructive:

Case I.—Boy, aged four years, referred for examination and opinion in December, 1895.

History given at that time by mother: During several years he has had attacks of respiratory distress of peculiar nature, getting worse lately. He has been seen by a number or physicians, who have called these attacks, variously, asthma and pneumonia. After exposure to cold the boy chokes up—nose occludes and throat seems to contract. Breathing is difficult, with marked wheezing. He becomes feverish, urine is lessened and cloudy, there is constipation. These attacks occur as often as once monthly, especially during cold weather. Between attacks he is seemingly all right, except for nasal occlusion. Because of the

[1] Gulland.

[2] Lennox Browne.

[1] Lister.

fear of the cold he is kept within doors and gets little exercise; he eats much and often, especially of meat; takes little water. There is marked constipation.

Examination: Somewhat undersized, but sturdy. Skin dry, especially of hands, which is cracked and rough. Peculiar worn appearance of face; mouth breather. Posterior rhinoscopy reveals a mass of adenoid vegetation filling the vault. The nose and rest of the tract are in fair condition; there is some secretion throughout.

Desiring to see the boy during an attack, I asked the mother to send word when he had another. This she did a few days later, but waited until the attack was nearly over.

December 20th, I saw the boy on second day of attack; he had then been in bed for nearly two days, with high fever and difficult breathing. When he was seen, respirations were through the mouth and frequent; the pulse was rapid and quick; temperature, 101° F. Auscultation revealed over the lungs nothing but wheezing respiration; over the heart a marked cardiac friction. Urine was small in amount, dark and heavy; micturition frequent. Urinary examination made next day: Hyperacid; specific gravity, 1.030; cloudy, loaded with urates; urea, 0.03 per cubic centimetre; uric acid and calcium oxalate largely in excess. I advised as follows: For the present, treatment to clear up acute attack. Later, when urine becomes normal, the removal of tissue in the pharynx, giving an opinion at this time that attacks would cease shortly after the vault was cleared and that the urine would clear.

December 26th, after short course of treatment, boy in good condition for operation. Large amount of adenoid tissue removed under chloroform. Tissue removed with forceps and vault scraped. Slight bleeding. Recovery prompt. Cardiac friction sound heard faintly before operating.

January 1st, doing well; friction sound has vanished. Urine clear.

January 15th, the boy seemed to be doing very well, when he had another attack. Not severe this time; no nasal obstruction. Urine scanty and thick, as before. He appeared brighter; skin not so harsh. Family physician reported that just after this attack the cardiac friction sound was heard again, disappearing after a few days. Examination: Pharyngeal vault clear; no secretion. Urine same as at first examination. At this time general treatment was advised, to meet the indications as shown by the urine.

March 1st, the mother reported that the child's general improvement had been marked. Skin softer, especially that of the hands; eyes clearer; still some constipation. One slight attack in February, severity lessening. Urine is free and clear.

August 1st, the boy passed from observation during the summer. Desiring to know his condition at this time, I sent for him. The mother reported as follows: Attacks have never quite ceased, lately getting more severe. He is constipated and urine is scanty. During marked constipation urine is in bad condition, and then an attack occurs. Eats well—much fruit, not so much meat as before. Plays out of doors. Examination: Pharyngeal growth in vault recurring; amount small, but covers whole surface of vault. Urinary: pale; specific gravity, 1.012; neutral; solids deficient.

At first sight, I thought that in this case the condition within the pharynx was the cause of the attacks and of the boy's general condition. After studying the history of the case since the operation, I have changed my opinion, and I now think that the general condition is the cause of the attacks and of the pharyngeal overgrowth. With this idea in mind, I made careful inquiry of the mother in these particulars—in regard to her care of the boy during the summer, in regard to his history since birth, and in regard to the family history.

In regard to care, he had received none of the general treatment previously prescribed during four months. Some attention had been given to diet and exercise, and he had had castor oil occasionally.

History from birth: When a baby he had slight wheezing respiration; severe cough from six months to teething-time. At about the same time he had constant diarrhœa; later, diarrhœa alternated with constipation. From three months to eighteen months, he suffered severely from an extensive eczema of face and head.

Family history: Both parents large, well-built persons. Father very hearty, and frank in regard to himself; admits having had gonorrhœa, but denies syphilis. No signs of immediate or inherited syphilis to be found. Always well; no rheumatism or constipation. Mother gives history of rheumatism. When a girl she had frequent sore throats (probably tonsillitis) and was always constipated. While carrying this child she suffered greatly from constipation, and was always ailing. Since then she has had muscular rheumatism.

The other case is given briefly. It is not necessary to quote a large number of cases, for all are much alike; and it is necessary to repeat only these two to show the points of most importance.

Case II.—Girl of eight years, with history of adenoid disturbance for years.

Family history: Mother gives nothing bearing upon case; father has very marked diathesis. He has had stone, and suffers from uric-acid and calcium-oxalate explosions; when a child he had croup. There are a number of children in the family, part of whom resemble the mother completely. Two resemble the father in every respect; both have croup; both are subject to uric-acid and calcium-oxalate disturbances.

History of child: Has croup each winter; whooping-cough some years ago; has constantly recurring periods of throat cough. Some time ago she was operated upon under chloroform for adenoid vegetations. She was at that time very delicate, with constant cough. She was better after operation until the fall, when cough recurred, and no treatment seemed to control it. She coughed more or less all winter.

Urinary examinations made at times when cough was most severe revealed urine loaded with uric acid and calcium oxalate, and was at same time of very marked acid reaction. Posterior rhinoscopy made last spring showed the following: Posterior pharyngeal wall covered with thick secretion, coming from the vault; adenoid tissue recurring in small amount in the vault; other tissues anæmic and relaxed. The child was pale and nervous. After trying everything, her cough was finally controlled at this time by giving her alkalies and complete rest in bed. There has been relief from the cough since then, and urinalysis shows a normal urine.

The condition known as adenoid vegetation involves a question: Is it merely a freak of growth, by which the normal limit of form is overshot, or is it due to some clearly defined cause? The condition is widely prevalent, it having been found in many races.[1]

Are we to infer, then, that this tissue is only remnant tissue—that it is tissue undergoing retrograde metamorphosis in the process of evolution? This is not yet proven; we are not warranted, therefore, in believing it can be so. I do not believe it for another reason. After operation, in cases in which there seems to be a direct cause for the growth, the removal does not suffice for cure. The growth recurs if there be no after-treatment. On the contrary, if the supposed cause is removed the growth does not recur.

[1] Wilhelm Meyer.

Having observed this close connection between cause and effect in many cases, and having observed the behavior of the growths under treatment, I believe that in every case there may be found a well-marked cause. It is well known that children of syphilitic or tuberculous parents have this growth. In these the cause is, without doubt, in the circulation. It is held by some that, syphilis having been present in a remote generation, its attenuation may be responsible for this condition in obscure cases. I do not believe this, for I do not believe that a syphilis diluted through many generations can hold its potency. I fail to understand, if it does, why its action is so manifest in this one direction, while in other directions it gives absolutely no sign. I believe, rather, that in these cases another circulatory cause is at work, that cause being an inherited diathesis. Why may not this be true? In growths due to syphilis or tuberculosis, is it not a specific poison within the circulation, or a vitiated blood, that is the cause? Why, then, may not some other circulatory irritant, or a vitiated blood from another cause, have a similar effect? That the diathesis is inherited is obvious. It is manifestly impossible that a diathesis can arise spontaneously in very young children. It must be inherited if it exists at this age, though I believe that a diathesis may be created in an older child without hereditary fault.

In an older, tougher organism, a diathesis is cause for much harm; in the young child the opportunity for harm is vastly greater. The child's tissues are more sensitive, the cell is more impressionable and responds more quickly to irritation. This is shown, especially, by the cells of the pharyngeal mucous membrane. They react acutely to the slightest cause; in fact, some pharyngeal irritation may be found in nearly all of their sicknesses. And this must be expected in a membrane so situated and so fashioned. Its structure is of extreme fineness, it is in intimate relation with all internal organs through the circulation and nerves, and it lies in almost direct relation to the external world It is wrought, therefore, by contending forces, and easily succumbs to irritation. It can be said, in truth, that the child's throat is a mirror, in which may be seen the reflection of his general condition.

In the cases quoted, the presence of an inherited diathesis is easily seen. Each reproduces almost exactly a condition found in one parent. In the first case, the mother has chronic constipation, with a history of rheumatism; and in the child the same tendency toward constipation exists, and we have also a variety of demonstrations of the presence of irritating matters in the circulation. During the attacks the urine was dark and heavy with solids; between attacks it was light in color and of low specific gravity. It can be surmised from this that in his ordinary condition his organs were not eliminating properly; that the substances usually removed by the liver and kidneys were being retained in the circulation; that at a certain stage of accumulation the organism rebelled and a violent paroxysm of elimination occurred. That this condition is a cause for the pharyngeal overgrowth is almost proven by this case, for do we not find the growth recurring after the vault was thoroughly scraped? And, furthermore, the urine remains as it was before the operation, showing that the circulation remains overcrowded with waste material. His condition was improved for a time following operation, which improvement was due to the operation and to the course of general treatment given him; but gradually he gets worse again, and upon inquiry we find that his mother has neglected his general treatment. For a period of four or five months he has had little of the proper attention. During that period the irritant has been left to circulate freely, with the result seen.

In the second case, the father and the child present the same conditions. During the diathetic explosions the same substances are found in the water of each, under the same conditions. In this case, also, the child was better after the operation; but after some months further demonstrations occurred within the pharynx. There was much secretion from the vault, with almost constant cough, and later new adenoid tissue is found in the old location.

IV.—While the cases given (especially the first) have been my inspiration in this idea, I do not hold that the two alone are proof beyond dispute; nor do I base my assertions upon these only. I have observed many similar cases, of which the two are types given for illustration. It is only by close observation of many cases that an etiology may be established. I would desire, therefore, other opinion upon the proposition of this paper. In my opinion, adenoid vegetations present a grave condition and one worthy of serious thought. I think that, with a proper understanding of the condition and its cause in the young, it may be prevented. I have worked with this thought in mind, and, while this paper may be incomplete and unsatisfactory, I hope at some future time to contribute something on this subject more worthy of consideration.

The urinalyses in these cases were made by Dr. A. E. Woehnert. Each was carefully made and complete.

466 Franklin Street.

THE MUNICIPAL CONTROL OF THE CONSUMPTIVE.[1]

By THOMAS C. CRAIG, M.D.,

passed assistant surgeon, united states navy.

Mr. President and Gentlemen of the National Sanitary Association: All sanitarians are naturally interested in the preservation of health by the prevention of disease; and I have no doubt that your association will do much, at this annual gathering, which will go far toward educating our people as to the rules and means to put into practice, whereby the spread of many of our infectious diseases may be limited.

One of the most prevalent and widespread diseases with which we have to deal is consumption, and it is to the municipal control of this disease that I wish to invite your attention for a short time.

Much has been written and proposed on this subject, but as yet nothing definite has been done. The municipal control of the consumptive is such a radical and far-reaching safeguard for the public welfare that the great wonder is that it has not long ago been put into practice. In and around the city of Brooklyn the annual mortality from tuberculosis is about fourteen per cent. of the total number of deaths. This large percentage is not alone confined to this area, but prevails with equal degree in many other places. The geographical distribution of this disease is greater than that of any other. Wherever you find civilization you will find cases of consumption; in the homes of the rich and in the homes of the poor, from the Arctic to the Antarctic, from the east to the west, everywhere this dread and persistent disease is present. No cure has yet been found for it; merely alleviation for those who have to endure the suffering, and then die.

This disease has been allowed to flourish in our midst unchecked and to claim its victims by the thousands annually, without there seeming to be anything done to limit its ravages or to call a halt in its

[1] Read before the National Sanitary Association, Brooklyn, N. Y., October 14, 1896.

relentless advance. Sanitarians, doctors, lawmakers, citizens, and officials everywhere sit idly by, and make no effort to enact laws and regulations for the control of this infectious disease. Consumption is commonly regarded as one of the diseases that we must live with, and if by chance one contracts it then it must be endured by him, while others run their own risks of becoming infected. Whole families have thus been carried off by one of their number having contracted this disease and in turn infecting all the remaining ones.

Municipal control very quickly asserts itself, should a case of leprosy happen to be discovered in any of our cities; yet when it is known that leprosy is far less infectious than tuberculosis, and that leprosy is not nearly so quickly fatal, the great wonder is that we have neglected for so long the more infectious of these two very similar diseases. Recently the view has been advanced by an able English writer that tuberculosis and leprosy are more nearly akin to one another than any other two diseases; indeed the theory has been advocated that they are twin sister diseases, several writers even going to the extreme of saying that they are identical, merely differing in their local manifestations by the different tissues invaded.

Attention is called to their resemblance: 1st, in their specific causation and in their morphology; 2d, in their pathology; 3d, in their distribution; 4th, in their general history and the conditions favorable or otherwise to their existence; and 5th, in their infectiousness.[1] This writer goes on to show that the same sanitary surroundings which tend to the promotion of one of these diseases will, in like manner, aid in the causation of the other one; that the same sanitary and climatic conditions go hand-in-hand to the production of effects which will aid these diseases to assert themselves. It is not my purpose to prove that these two diseases are similar or dissimilar, but to draw the parallel of comparison as to how eager we are to take control of the leprous subject, when at the same time the tuberculous patient is allowed to roam at will. If municipal control of the leprous subject is for the safeguarding of the health of the community, why then do we not make the health of the public yet more secure and safe from infection by taking under control the cases of tuberculosis? In answer to this I may say that it is because the breaking of family ties, the removal or restraining of those we love, and the taking away of friends would lead to sorrow and grief. Yet these things are disregarded in the case of the leprous patient.

I am not yet prepared to advocate the forcible removal and control of all persons affected with consumption by the municipal authorities, and the placing of them in suitable sanatoria, so that the dangers of infection would be lessened, but this would be the plan by which the remainder of the community would be rendered safest from infection. To all this the public will have to be gradually educated and enlightened, and until that result is attained other kinds of municipal control might be used. That the proper control by the municipal health officer would decrease the number of cases of tuberculosis there can be no doubt. That our people can be gradually taught these things there can also be no doubt, but until this can be accomplished, the common ordinary rules of sanitation and control which are now exercised in many of our cases of infectious diseases can be brought to bear on this class of patients.

That tuberculosis is a highly infectious disease, and that it annually causes more deaths than any one other disease, no one will dare to deny. The infectious nature of this disease had been known for a long time, but it was not until 1882 that it was definitely ascertained to be due to a specific organism.

[1] London Lancet, July 11, 1896.

Experimentation has since shown how very easy it is to induce this disease in some of the lower animals. If a small particle of tuberculous sputum be inserted beneath the skin of the guinea-pig, the tuberculous process can with certainty be established in about three weeks. Of course this particular animal is very susceptible to this particular disease, being much more so than human beings; and this now brings up the question as to who are susceptible and who are non-susceptible to tuberculosis. Why are some persons immune while others are non-immune?

When it is remembered that most all known diseases depend for their development on the weakened resistive power of our body cells, or in other words on the power of our body cells to battle against the attacking power of the bacteria which cause disease, it is easy to arrive at the comparative fact that whatever lowers our resistive power will aid our enemy, the bacteria. It is the food we eat, the air we breathe, and the clothing we wear which enable our body cells to maintain their tone or strength. When these things are in improper proportion or are of poor quality, then our body cells suffer; they become weak, are unable to resist the attacking power of the disease-producing bacteria, and as a result we are liable to contract some one of the diseases.

It goes without saying that the more widespread any certain disease-producing bacteria are, the more cases of that disease there will be, provided, of course, there are plenty of non-immune subjects present and they are exposed to these infecting bacteria.

In this one disease, viz., tuberculosis, over which it is urged there should be municipal control, I am certain that the number of cases could be greatly lessened annually. The number of areas of infection could be reduced, good food could be supplied, proper ventilation could be instituted, and, to the poor, clothing furnished. Municipal control of the consumptive need not mean the same control as is exercised over a prisoner. At first it might be merely a control over his place of residence; as, for example, where there might be a consumptive patient who was compelled by personal or by financial reasons to eat, live, and sleep in the same room with healthy persons; or where it might be impossible for him to give up his employment and necessary for him to go to and from his place of business in public conveyances, or necessary for him to meet many persons daily in the conduct of his business. It is in these places and at these times that the consumptive cannot, by force of circumstances, or is not, by force of habit, overparticular as to whom he may or does infect with the disease he himself suffers from. The expectoration of a consumptive person contains millions of the tubercle bacilli, and in his going to and coming from his place of business this sputum is deposited on the street or on the matting and upholstery in cars and carriages, on table napkins and towels, both at home and in public eating-houses, there to be dried and then blown about as dust and inhaled by others. Ladies with their long trailing dresses unconsciously sweep up this tuberculous sputum on our streets, and it is carried home into their houses, there to dry into dust and possibly infect some member of the household. It is largely to ignorance of these facts that we owe many of the cases of consumption. Probably no more dangerous sources of infection exist in our towns and cities than the street cars with their mats and matting. These things form excellent and handy places for the consumptive to deposit his expectoration. It sinks into them, dries into dust, and in a short time is ready to be inhaled by some one who possibly has had his resistive power lowered by sickness, or by exposure, or by want of food, or by overwork; and the result is, in many cases, infection.

No child was ever born with consumption, but yet it is true that annually many children die of this disease. How, then, do they contract it? I answer, that they are infected by tuberculous mothers, or by tuberculous nurses, or by coming in contact with tuberculous persons, or by inhaling germ-laden dust.

The question as to whether a tuberculous mother should be allowed to nurse a healthy child may in the future come up for the municipal health authorities to decide, as may also the advisability of allowing consumptive persons to use public conveyances.

The question of the sanitary regulation of the cleanliness and the healthfulness of our public conveyances may yet be placed under the control of the proper municipal officer, and we will not be confronted with notices such as "Gentlemen are requested not to spit in this car;" but we will see in its place the following: "Any one who spits in this car will be arrested and prosecuted." By the municipal control of the consumptive many of these dangers could be avoided. The municipal health officer would then demand that all cases of consumption be reported to him. He would then send an experienced assistant to the place where the case existed. This assistant would satisfy himself as to the condition and sanitary surroundings of the consumptive subject, and also as to the general understanding the patient had concerning the danger of infecting others; he would also take note of the number of persons living in the house, the general sanitary conditions, and of the health of these persons, and then report these facts to his chief. Measures could then be taken to confine the disease within the smallest possible area so as to run the least possible chance of infecting others. The houses or rooms which were occupied by consumptive persons could be reoccupied or allowed to be rented for occupancy only after having been thoroughly disinfected, and this disinfection, too, could be carried out under the supervision of a competent and conscientious person. All furniture, bedding, clothing, carpets, rugs, etc., which were used by a consumptive person could be properly disinfected.

The control of the sanitary condition and the compulsory disinfection of our street cars and public conveyances should be brought under the authority of the municipal health officer, by the enactment of proper laws for the preservation of the public health. Very few persons have any idea what a large factor in the causation of consumption by infection the dirty, dusty street cars and public conveyances are. Within the past couple of years inoculation experiments made, both in this country and in Europe, with the dust and sweepings from these vehicles showed the presence of the tubercle bacillus in a large proportion of the cases.

Have you ever thought about what travelling areas of infection our richly upholstered sleeping-cars which run to and from our health resorts for consumptives are? Imagine a consumptive person riding for a day or two in one of these cars, staining the floor, carpets, and the upholstered seats with his tubercle-laden sputum, and then unknowingly this same compartment soon occupied by a weakened delicate person, who unconsciously might inhale some of these tubercle bacilli and thus become infected by the disease.

Cases like this could be multiplied, as for example, in the berths on steamers, the bedrooms in hotels, etc. It is just in these kind of places of infection that the authority of the municipal health officer should come in for the control of the sanitary condition of these means of travel.

The guarding of the public health is what we charge the municipal health officer with, yet we fail to enact the necessary legislation by which he can accomplish this end. The cities of New York and Brooklyn have within the past few years made an attempt to locate their cases of consumption and also to point out, by very excellent circulars, the dangers of infection by the consumptive, and how to guard against them. But necessarily they leave it optional with the physician to report these cases or not to report them.

These circulars are requestive. The health boards of these cities also offer to disinfect all furniture, carpets, rugs, clothing, rooms, etc., free of cost, if the persons will only come forward and agree to it. But all this is futile for good as yet. The reporting of a tuberculous case should be mandatory, and for the neglect to do this a heavy fine should be imposed.

No excuse should be taken that the physician is unable to diagnose with certainty a case of tuberculosis. The microscope furnishes a ready and positive means of ascertaining whether or not a sputum contains tubercle bacilli.

When the municipal control of the consumptive patient is given to the health officer, then it will be that the number of cases of that disease will begin to decrease. The municipal health officer can then make the proper regulations for governing the going and coming of the consumptive; the friends and relatives will readily consent to any humane and wisely directed rules when they know that these same rules are merely intended for the safety of themselves and others. Living-apartments, furniture, and clothing will then be rendered free from infection; street-car companies, owners of public conveyances, and railroad corporations will then have to disinfect their cars and vehicles thoroughly as often as it may be necessary.

I am convinced that this municipal control of tuberculosis should also extend to the milk and meat supply. Tuberculous cows, and cattle intended for meat, should be rigidly excluded from our markets.

Systematic and regular inspections of all of our dairy farms and of our meat supply should be carried out by our municipal health officers, and all means should be taken to exclude these sources of infection.

The general public may at some future time be educated up to the necessity for all these things, and the result will be fewer cases of consumption, less danger of infection to the public, less suffering, longer life, and in the end more prosperity.

Every one will then agree that the prevention of disease is better than the cure.

109 West Street, New York

Operations for Facial Neuralgia.—Dr. Louis McLane Tiffany says, in the *Annals of Surgery* for November, 1896, that with our present knowledge it is not always possible to say what case will require a central operation, but the following suggestions will assist the surgeon in deciding: 1. Intracranial operation is to be thought of—(*a*) if more than one branch is affected; (*b*) if the painful area receives filaments from the branches near their exit from the head, *e.g.*, tongue, temporal region; (*c*) if the pain is not the expression of a constitutional disease; (*d*) if a cause central to the ganglion does not exist; (*e*) if other measures have failed to relieve. 2. The intracranial operation for the cure of facial neuralgia which should be done is removal of the lower two-thirds of the ganglion of Gasser, together with the second and third branches as far as their foramina of exit from the skull, all in one piece, so as to be certain of the amount of tissue taken away. 3. The upper third of the ganglion and first branch may, for the present at least, not be excised for neuralgia. 4. It may confidently be expected that the present large mortality will be greatly diminished by the adoption of an improved technique joined to increased experience.

Clinical Department.

MICROSCOPICAL POWER OF THE NATURAL NORMAL EYE.

By F. L. O. ROEHRIG, M.D.,

PASADENA, CAL.

Some time ago, while attending to my morning toilet, I happened by mere accident to look in an almost perpendicular direction and at a distance of an inch or two, more or less, down on to my beard—the mustache as well as the whiskers surrounding my chin. How great was my astonishment at the strange and unexpected appearance of what I then saw! Every hair greatly magnified, just as seen through a microscope. Each hair stood out plain and distinct and as though forming a tube which, according to all appearance, was transparent, rather colorless, hollow and empty, bounded, as it were, on both sides, by a generally well-marked bright white line or border. The size of the magnified hair-tubes varied from that of an ordinary darning-needle to the volume of a small lead-pencil; it increased gradually in proportion as I moved those tubes slowly upward from the chin: and it seemed to reach its maximum when seen nearly high enough to be somewhat on a level with the eye, or right opposite to it.

I likewise examined the very thin and short hair on my hand and fingers, and the result was just the same. Then I plucked out a hair and held it between the fingers, with invariably the same result.

The experiment succeeded as well in daylight as in artificial light. Monocular or binocular vision seemed to make no essential difference. Dark as well as light hair, red and gray or white hair, served the purpose equally well.

I could, moreover, render this magnified appearance perceptible to other persons, with the same clearness with which I saw it myself.

Finally, I took a thick hairlock from a child's head and held it up to my sight, when a very large mass of strongly magnified intertwined tubes, like a network of strings or cords, was at once seen. It increased in size considerably, in proportion as I moved it slowly upward; it reached its maximum when it had come high enough to be in front of my eyes and was held there at a distance of an inch or two, more or less. At last I tried the experiment in a darkened closet, where, through a longitudinal slit, I let in a stream of very bright sunlight. Every one of the hairs of my whiskers appeared considerably more enlarged than ever before, and the inside of nearly all those magnified hairtubes seemed in their whole length, as it were, lined with numerous fine longitudinal parallel strokes, somewhat similar to the shading of a pencil drawing. One or two of those tubes appeared in beautiful rainbow-like colors.

I also tried these experiments with the additional aid of a reflector, when I obtained the same magnified appearance of the hair tubes.

Then I extended my observations to various small objects, such as horsehair, blades of grass, needles, minute insects, etc. The result was invariably the same. The best view, however, was presented by longitudinal objects, such as needles, strings, etc. At last I resorted to magnifying glasses in order to find out whether and in what manner or degree the appearance of the objects examined would differ from that observed by the microscopical power of the naked natural eye. This served to confirm the entire results.

The eyes of all those whom I made to see just what I saw, as well as my own, are perfectly normal in every respect. Persons whose sight is not defective can, without any effort or sense of strain, at once perceive those magnified appearances. Almost every one will find, at first, some slight difficulty in so doing. Those, however, whose visual powers are, even in the least degree, vitiated by anything anomalous or abnormal, such as myopia, presbyopia, hypermetropia, astigmatismus, staphyloma posticum, etc.—in short, by anything that in the domain of ophthalmology would come under the head of morbid states or pathological conditions of the eye—cannot reasonably be expected to possess or acquire the necessary aptitude for these microscopic perceptions.

He must also distinguish between this constant, continuous, and permanent microscopic power and those merely accidental and transitory states of morbid exaltation of the sight that are known as oxyopia and megalopsy, in certain diseased conditions of the eye. Moreover, imagination, as it may probably be urged, fancy, or self-deception are altogether out of the question in this case; since the phenomena under consideration can be reproduced at will and may be verified at any time by any one. The fact for the present is simply stated, without hypothesis or explanation. It may be experimentally demonstrated as an objective reality. In all probability there exists some law resting on physiological optics, and, as it were, on the very constitution and mathematics of the eye, which will explain all.

Like many other things in nature, the fact here presented could have been very easily overlooked in the past, and escaped general notice: it has, perhaps, never come, heretofore, under observation. Still, we should not indifferently let it pass altogether unnoticed; for all this may be merely a first step in a whole continuous series of connected subsequent facts and may thus gradually lead to perhaps many, as yet, wholly unexpected important scientific truths and variously valuable new discoveries.

402 South Oakland Avenue.

RECURRENT TUMOR OF SLOW GROWTH.

By D. D. CHASE, M.D.,

MONTICELLO, N. Y.

About sixteen years ago, Mr. L. E. C——, aged thirty-six, merchant, of good health and habits, noticed an insignificant crusted excrescence upon the left side of the nose, near the inner angle of the eye, removal of which caused oozing of slightly bloody serum and was rapidly followed by another scab or crust. In the course of a few years it began to excavate the parts, involving the skin only until surgical interference was begun. About one square inch of skin was taken from that part of the nose, together with about one-fourth of the inner portion of the lower eyelid. Transplantation with a flap from the forehead stayed the process for about four years. At the expiration of this time the disease began again on the normal skin, but not in the flap. After suffering much pain for a year or more, the patient tried Koch's lymph, at first with apparent good results; but increasing doses failed to heal the ulceration completely, and this method was abandoned.

Early in 1895 there appeared a soft tumor, about three-fourths of an inch from the nose and the same distance from the margin of the under eyelid. By July it had reached the size of an English walnut, closing the eye by its pressure and thickening of the adjacent skin. At this time another plastic operation was done, in a New York hospital. There was an opening into the antrum, the floor of which was roughened. The wound healed by first intention, and in a few weeks the patient returned to his home. In October there appeared upon the malar prominence small erosions, as also upon some parts of the transplanted

integument. Another operation was done by the same surgeon, about October 10th. In March, 1896, the growth again appeared, but by the advice of competent surgeons it was thought best not again to resort to surgery; therefore, from that day the tumor is a series of nodular masses, making a general elevation of about four inches above the plane of the cheek, covered with brown crusts. It closes the orifice of the ear, extends one inch below the submaxillary bone, and crowds the nose over to the right of the median line. Bleeding, which is sometimes very profuse, is stopped by the free application of Monsel's powder. The surface has been dressed daily for the last six months with linen saturated with Pinus Canadensis for cleanliness. Though suffering great pain, the patient keeps up good spirits and appetite, and the mind is clear.

A CASE OF SECONDARY CANCER INVADING THE LIVER, STERNUM, AND VERTEBRÆ, WITH A GROWTH IN THE SPINAL CANAL CAUSING PARALYSIS FROM PRESSURE.[1]

By B. C. LOVELAND,

CLIFTON SPRINGS, N. Y.

Mrs. C. S——, fifty years of age, was brought to me on May 12, 1896. Her condition at that time was as follows: Great emaciation, a marked antero-posterior curve in the spine, extreme distention of abdomen with gas, so that it was impossible to ascertain the condition of any of the internal organs, a condition caused largely by a paralysis extending from the middle of the dorsal region downward. There was paralysis of both bowels and bladder, and complete anæsthesia of the lower extremities extended upward as far as the distribution of the sixth dorsal nerve. There was a good plantar reflex, and jerking of the extremity could be elicited by tickling the dorsal surface of the foot or by pricking the leg. There were frequent painful contractions of both lower extremities, which seemed to arise from the irritation caused by flatulence. Respiration was labored, and often as frequent as 40 per minute; pulse ranged from 95 to 120 per minute and temperature from normal in the morning to 100° or 101° F. in the evening. A large scar marked the site of an operation for the removal of the right breast and axillary glands, and there was a small nodule of the size of a walnut in the axilla in the line of the incision. Patient complained of much pain in her limbs and in her back between the shoulders. She gave a history of tuberculous ancestry and had had a chronic cough for years, but no tubercle bacilli were found in her sputum. The first disease that might be connected with her condition at the time was a cancer of the right breast, which was removed in 1889, and a second operation for a growth in the cicatrix was performed by the same surgeon in 1891. Since that time she had enjoyed good health until two and one-half years ago, when she began to suffer with what were called rheumatic pains in her right leg, and the leg soon became practically helpless or paralyzed. Her general health remained good, however, until April last, when an increase in the lameness occurred, and the pain and paralysis attacked the other leg, progressing rapidly until the condition was reached which I have above described. The cause of the trouble in her lower extremities was attributed to a rheumatic neuritis by the physicians who had examined her before I saw her, and it was some days before her intestines were sufficiently free from gas to permit of a satisfactory examination. By careful diet and frequent flushing of the bowels with the long tube, the flatulence was sufficiently reduced to allow of a more careful examination. The liver was then found to extend to a line three and one-half or four inches below the ribs, and to be dotted all over the surface with hard nodules. This, of course, meant secondary cancer, and gave probability to my idea that her paralysis was caused by a neoplasm in the spinal canal. At that time Dr. Lichty examined her with me, and we concluded that the paralysis was from pressure; but, with her history, it seemed uncertain whether the pressure was from tuberculous or cancerous disease. Her temperature also pointed to a possible tuberculous complication. About this time, examination of her urine showed albumin and casts, both hyaline and granular. The patient lingered along with little change in her condition, except a gradual weakening and occasional delirium, temperature and pulse remaining about the same, until August 28th, when she died. Report of the autopsy is as follows: Body emaciated, abdomen slightly distended, legs œdematous, sternum bent so as to look like a dislocation of both segments, the upper segment being drawn forward and upward, pulling the lower one with it. Great increase in dorsal curve of the spine. Spinal cord compressed at point of third dorsal vertebra by a solid growth projecting into the spinal canal from its anterior wall. Vertebræ softened. Sternum softened, with cancerous infiltration. Left lung broken down at apex. Right lung filled with hard material. Heart normal. Liver filled with cancerous nodes, many of them an inch or more in diameter. Intestines normal. Left kidney: capsule somewhat adherent, red, granular, contracted. Right kidney: capsule free, red, granular, contracted. Both suprarenals softened and degenerated. Stomach not thickened, but contracted to about the size of the small intestine for four or five inches nearest its pyloric end. On microscopic examination the growth in the spinal canal was found to be cancerous. This case presents two or three peculiar features, viz., the long time that followed the final operation on the breast before the secondary development in the viscera occurred; the broad distribution of the disease, even invading the spinal canal: and the length of time between the first operation and the final triumph of the disease.

[1] Read before the Ontario County Medical Society, October 12, 1896.

ROENTGEN RAY TRAUMATISM, WITH REPORT OF A CASE.

By W. B. BANISTER,

CAPTAIN AND ASSISTANT SURGEON, U. S. A., FORT COOK, NEB.

On April 15, 1895, Capt. John McA. W——, U. S. A., was accidentally shot, the ball entering the back in the lumbar region, to the right of the spinal column, grooving the crest of the ilium two inches from the spinous process of the lumbar vertebra, and passing upward and inward, but not emerging from the body. Immediate paralysis from the waist downward resulted. There was slight sensation in the left foot within an hour or two after the injury, and the patient was able to lift the left foot within two or three weeks. In three weeks he began to have acute pain in the right leg, but could not move it, and was confined to bed for eleven weeks. After that time he could use a crutch, and there has been steady improvement ever since. When he left this post, about August 10, 1896, the use of the left leg was not impaired, but there were paresis of the flexors of the right thigh supplied by the anterior crural nerve and some atrophy; but with the aid of a cane he could walk fairly well, and had difficulty only in ascending steps. The bullet evidently ploughed its way through the dense lumbar fascia and muscles, until arrested in its course by the spinal col-

umn. The patient had been improving steadily for a year. There was, therefore, no good surgical reason for attempting its removal, even if its location was known, as the manifestation of nerve injury had resulted directly from the traumatism and had been progressively improving.

When *en route* to this post, he stopped in Chicago to consult a surgeon about the paresis of the flexors of the right thigh, and was advised to have the bullet skiagraphed at a certain Roentgen-ray laboratory in Chicago, with a view to operative procedures for the relief of the paresis, on the supposition that the bullet was pressing upon the anterior crural nerve.

On August 11th and 12th he had three exposures of one and one-half hours each, making four and one-half hours in all that the tissues of the skin were subjected to the action of the rays. As far as locating the bullet was concerned, the result was negative. Some redness of the skin resulted, but not sufficient injury to the integument to cause any inconvenience. We may conclude, therefore, that the integument can stand an exposure of four hours, divided between two successive days, without material damage.

Again, on September 9th, 10th, 11th, and 12th, in eight sittings, the patient underwent a total exposure of nearly twelve hours. There were no results as far as locating the bullet was concerned, but there were other results that left the patient a sadder and a wiser man. On the first day the skin began to show signs of inflammation, which extended each day during the trial.

I examined the patient a day or two after his return to the post on September 13th. The Crookes tube during the exposure was held a little below and to the right of the umbilicus. In that situation the epidermis had been destroyed for a space of about one-half the size of a man's hand, leaving the red, inflamed, and hyperæsthetic cutis vera exposed, and the outpouring of serum was very profuse. A red blush extended from this centre in every direction, but principally to the right of the median line and from below upward. The death of the epidermis rapidly extended, and large blisters, such as occur in scalds, formed beneath it, and in a few days the denuded rectangular surface measured eight by fifteen inches, the longest diameter being from above downward.

The superficial layer of the cutis vera is now being thrown off, leaving a raw, bleeding surface, and the quantity of serum (with some pus) that exudes is astonishing. The lesion extends upon the thorax to the level of the right nipple. The patient has been confined to bed for a month, and the denuded surface is so hyperæsthetic that he cannot stand the application of gauze and absorbent-cotton dressings, and it has been necessary to cover the surface with perforated gutta-percha tissue. Drying and astringent powders seem to have no effect in checking the outpour of serum, which is quite an annoyance to the patient. The patient's beard is naturally of a dark-brown color, but since the prolonged exposure to the rays no beard at all has grown on the chin, where formerly a goatee flourished, and the rest of the beard on the right side, which was in the line of the rays, has turned white or light yellow. The integument of the chin was reddened, but the epidermis was not destroyed. During the exposure the patient sat with the right hand grasping the rounded end of the arm of a chair. It can be readily seen by trial that if one grasps with the right hand the arm of a chair in a natural pose, the dorsal surface of the fingers turn outward and forward, while the dorsal surface of the last phalanx of the thumb turns forward and inward, and in that position would be impinged upon by the *x*-rays at a right angle; at least, that is the only explanation of the fact that the integument over the dorsal aspect of the last phalanx of the thumb was reddened, and it seems quite likely that the nail will be lost. It would seem that the rays impinging upon the tegumentary surface at very acute angles produces no irritating effects, for the curved lateral aspect of the abdomen—which must have been impinged upon by the rays, inasmuch as the thumb, which was still farther removed from the focus of irritation, was affected—showed no signs of irritation. The intensity of the irritation seemed to be in proportion to the approximation to a right angle at which the rays impinged upon the tegumentary surface. In that respect they seem to resemble heat rays. Since the *x*-rays pass through the body, is it not strange that no irritating effect is produced upon the peritoneum, a much more delicate membrane than the skin? This fact would lead me to believe that the inflammation of the skin resulting from the *x*-ray is due to its action on the terminal nerve filaments in the skin, probably the vasomotor nerves, as the structure that receives the full intensity of the rays is the only one affected. It is, therefore, a change in the nutrition of the tissues. Over six weeks after reception of the lesion, the pain is agonizing, burning in character, and necessitating the use of morphine. Oxide-of-zinc ointment, etc., do not control it.

The patient wore a light-weight cotton undershirt during the exposures, and felt no heat nor pain during the passage of the rays through the skin. This absence of apparent effect might in itself be a source of danger in using the *x*-rays about the face, as it can readily be seen that it might so seriously inflame the delicate conjunctiva as even to imperil the integrity of the cornea. Again, it might cause the permanent loss of eyebrows and eyelashes, and so disfigure the patient. Should not this injury to the integument necessitate the very cautious use of the *x*-rays on a part suffering from a severe traumatism, especially as the additional injury to the integument might have a very unfavorable effect on the result of subsequent operative procedures? On the other hand, the *x*-ray might with great advantage be used to remove hairy growths for a cosmetic effect, and with a good prospect of the hair not returning; at least, the goatee referred to shows no sign of a return to its former habitat, and it would appear an easy matter to remove the hirsute appearance of the upper lips of some young ladies, which is so often a source of mortification. It would be advisable when they are used for that purpose to employ a screen impenetrable to the rays to prevent injury to other tissues. It is claimed that the haloid salts obstruct the *x*-rays. Captain W—— has been confined to his bed for a month now, and will probably be so another month. The prolonged use of the *x*-rays in cases in which no good can result, as in this case, is much to be deprecated, as it would become a very serious question in economics to a man to be bedridden for two months unnecessarily when his livelihood depended upon his ability to work. There is a great temptation to remove foreign bodies, even when doing no harm, when found by the agency of the *x*-rays, as it impresses the patient and his friends with its brilliancy, and for its advertising advantages the temptation will most likely be often yielded to. Several claims have been made as to the potency of the *x*-rays in destroying bacterial life, but the most recent experiments demonstrate that its effect is negative in that direction.

Locomotor Ataxia.—The value of the discovery of Motschukowsky in the treatment of locomotor ataxia will not be appreciated to its full extent by the profession at large until permanent suspension by means of the extension corset has replaced temporary suspension.

Surgical Suggestions.

Hemorrhoids.—Calomel dusted upon external piles causes them to disappear. Internal hemorrhoids are treated with ten-per-cent. calomel ointment. The itching is relieved at the same time. Opium or belladonna may be added.—Nægeli-Ackerelom.

Erosion of Cervix.—Boroglyceride tampon.

Inflamed Breasts.—

℞ Boric acid..... ʒ i.
Glycerin..... ʒ i.
Water..... O i.

Aortic Aneurism.—Bodily overstrain is the principal etiological factor in its production. Platinum may be inserted in the sac to bring about coagulation.—Lutten *and* Leyde.

Drainage is not always necessary after abdominal sections, unless there is much oozing. Irrigate with a normal salt solution (one drachm of salt to one quart of water at temperature of 105° to 110° F.), if there is much oozing, use it at 115° F. If a drainage tube is used, it should be removed and emptied every half-hour or so, under strict antiseptic precautions.—*Jefferson Clinics.*

Sacculated Kidney.—Conservative operative treatment is advised. In order to save a cystonephrotic kidney, many operations, extending over a long period of time, are necessary. Nephrotomy in given cases would mean death. Patience and energy may save the patient from the social misery accompanying urinary fistula. In unilocular hydronephrosis the operation for bisection of the sacculated kidney is, of course, not required, and only nephrotomy, the operation for valve formation in the ureter, and that for closure of the kidney, are needed.—Fenger.

Indications for Nephrectomy.—1. Tumors of the kidney. 2. Tuberculosis of the kidney. Experience has shown that renal tuberculosis occurs very often primarily and unilaterally; it affects the genitals and the lower urinary passages more frequently than some other parts of the body. Severe persistent catarrh of the urinary bladder is one of the first symptoms which tuberculosis of the kidney presents; in cases of this kind nephrectomy gives excellent results and complete recovery ensues. 3. Suppurating kidney caused by metastatic processes and foreign bodies, especially calculi. 4. Renal hæmophilia. 5. Movable kidney. 6. Injury to the kidney. 7. Calculous diseases of the kidney. 8. Uretero-abdominal fistula.—Dr. Kuster, *British Medical Journal.*

Hemorrhoids.—Dr. Cole (*Atlantic Medical Weekly*, November 9, 1896) thinks that for the removal of piles which are between the sphincters, or the external venous tumor, the split operation is the best. This operation consists in removing a narrow strip of membrane from the top of the tumor, and either rolling out the clot in the acute external one or cutting out the internal redundant areolar and mucous tissue, which may be softened or more or less disintegrated. This split operation requires an anæsthetic and complete dilatation of the sphincters. French surgeons have recommended sewing up the split after removing the pile tissue, and this gives good results when there is not much tissue to be removed. Piles of the acute external variety, which are hard, hot, and painful, and always contain a blood clot, may be quickly split open and the clot rolled out. Cocaine may be used as an anæsthetic.

Turpentine, it is said, will remove the odor of iodoform from hands and instruments.

The Commercial Value of a limb nowadays deserves the serious consideration of every surgeon.—Lane.

Vegetations about the Vulva.—Equal parts of powdered savine, iodoform, and salicylic acid make a powerful application.—Lutand.

Mineral Astringents.—Never use a mineral astringent when a woman wears a pessary, as it is liable to deposit on the pessary and set up an irritation of the parts.—Rosenberger.

The Extension Corset acts like a plaster corset, and is constructed according to Sayre's method, except that steel bars and French *coutille* are used instead of plaster. It fits as snug to the body as a plaster corset, and its parts form an outer skeleton, to the inner side of which the muscles of the trunk adhere closely.—A. C. Wiener.

Burns.—A saturated solution of nitrate of potassium is recommended by Poggi for burns of all degrees, for its refrigerant and antiphlogistic properties. The quality of the bath is maintained by the addition from time to time of a few teaspoonfuls of the nitrate. After two or three hours the pain generally disappears, after which compresses wet in the same solution may be applied.—*Thèse de Paris.*

Transfusion, Infusion, and Auto-Transfusion.—Dr. Schachner (*American Practitioner and News*, October 31, 1896) gives the following as his conclusions: 1. In enormous hemorrhages the resulting dangers are more frequently due to the reduced intravascular pressure than to the actual loss of blood. 2. In view of this the indications point more decidedly toward infusion than transfusion. 3. That transfusion has not received the attention which its merits justify. 4. In transfusion we possess a measure which in the severest hemorrhages is the only agent capable of restoring the vital functions. 5. The indications for transfusion include any condition which reduces the total quantity of blood to a fatal degree, or which alters the character of the blood to such an extent as to render it incapable of carrying on life. 6. When the transfusion is performed for the relief of a poisoned condition of the blood, it should be preceded by venesection. 7. Centripetal is to be preferred to centrifugal transfusion. 8. In centripetal transfusion the injection should be made with a slow, steady stream, carefully exercising no undue force. 9. In withdrawing the blood from the donor the veins afford an easier, safer, and better source than the arteries. 10. Indirect transfusion with defibrinated blood is safer than direct transfusion with non-defibrinated blood. 11. In alarming hemorrhages infusion should be performed before transfusion; should, however, the improvement be transient in its nature, the infusion must be supplemented with transfusion. 12. In addition to hemorrhage, the indications for infusion include any pathological state attended by a feeble pulse which is dependent upon a relaxed condition and a diminished intravascular blood pressure, namely, shock. 13. Restoring the tone of the circulation by infusion is not wholly dependent upon the increase of the intravascular pressure, but is in part due to the stimulating influence which salt solution has upon the heart. 14. In performing transfusion or infusion after an enormous hemorrhage, the use of an anæsthetic is not only unnecessary but absolutely dangerous. 15. In the autotransfusion we have a valuable measure for combating shock and preventing accidents in anæmic subjects during chloroform narcosis.

Opening the Pericardium.—Incision of the pericardium may be practised for tuberculous pericarditis. Rosenstein's incision may be followed. The skin, fascia, muscles, and endothoracic fascia are successively divided until the pericardium is reached. The latter is then seized and drawn out of the wound and fixed to the edges of the latter with two sutures (Gussenbauer). The pericardium is then opened with a narrow knife or pointed scissors, the incision being subsequently enlarged, if necessary, by the probe-pointed bistoury. The opening in the pericardium need not be larger than the drainage tube which it is proposed to employ.—George R. Fowler.

Outstanding Ears.—Dr. Joseph, of Berlin, has recently operated upon deformed ears in a patient eleven years of age, removing a portion of the upper part of the ear and stitching the margins of the wound. He then removed a flap from the posterior portion of the ear, and fastened the organ to the side of the head. This is spoken of as an entirely new operation, whereas it has been practised for deformity of the ear in this country for a number of years. Dr. C. W. Allen presented a child some three years ago at one of the societies, in whom a pronounced deformity had been successfully corrected by such an operation, and other cases have been recorded.

Resection of Lung.—Resection of lung or pneumectomy would appear at first glance to be a rational method of procedure in tuberculosis of the pulmonary structure. Surgeons who are accustomed to practise resections of the articular extremities in tuberculous osteoarthritis, and extirpation of the synovia in tuberculous synovitis—and who have witnessed the gratifying results following these operations—are at once impressed with a desire to institute radical operative methods in a disease which counts its victims by thousands yearly. The pulmonary structure, however, differs from all other structures in the body in its susceptibility to infection by means of the bacillus tuberculosis, and its anatomical peculiarities are such as to favor extension of infection and reinfection of parts whose vital resistance has been lowered by disturbances of nutrition from any cause.—G. R. Fowler, *Annals of Surgery*, November, 1896.

Extirpation of the Rectum.—Among the advantages of the vaginal method might be mentioned the following: 1. The vagina can be made to take the place of the extirpated portion of the rectum. 2. The excision can be done as high up as by the sacral method and with less traumatism, and in case the peritoneal cavity is opened with less danger. 3. An intraperitoneal exploration of the tissues about the rectum can be made before disturbing the rectum. 4. If the operation has to be abandoned after the incisions are made, the wound is less formidable and in a better place. 5. The patient is more comfortable after the operation than after the sacral methods. Price's abdominal method possesses nearly all of these advantages, but is more dangerous, necessitates a removal of the uterus, and cannot be adapted to cases extending low down in the rectum. McArthur's method is more dangerous in cases high enough up to involve an opening into the peritoneal cavity, and in all cases involves more traumatism.—Henry T. Byford.

Nitrous-Oxide Gas with Oxygen in removal of adenoids has the advantages that: 1. It is not attended with danger to life. 2. No preparations are required. 3. Hemorrhage is not affected by it. 4. Jactitation and cyanosis produced by pure nitrous oxide are absent. 5. Any position may be safely assumed. 6. Anæsthesia is longer than by the nitrous oxide alone. 7. Unpleasant after-effects are very rare.—Gardner.

Hydrarthrosis.—In this age of asepticism, to sentence an unfortunate bread winner to a term of two, four, or six months on splints or on his back, for "water on the knee," is, to my mind, an unjustifiable and unsurgical procedure.—John O'Connor.

Encephalic Abscess.—The treatment can be but surgical, every patient bearing such a lesion being condemned to death after a more or less brief delay.—Luc, *La Méd. Mod.*, November 7, 1896.

Endometritis.—I think that impregnation is more likely to follow when curettage and tamponade have been employed for the cure of endometritis than after treatment by other methods.—Basham.

Chloride-of-Ethyl Spray directed into the alveolar cavity stopped severe hemorrhage after tooth extraction. The cavity was then filled with cotton wet with tincture of hamamelis.—*Gaz. Méd. de Liége.*

Lupus.—Dr. Stieda reports two cases of lupus and one of tuberculosis treated by excision of the diseased areas in several sittings, and the application of a Thiersch graft after each operation. If possible, the whole area should be excised at a single sitting. Upon the face a small amount of panniculus adiposus should be left. Warm sterile water without antiseptics is used at Tübingen. Grafts must be as large and as thin as possible, and the dressing is to be changed on the third day.—*Beiträge z. klin. Chir.*, B. xv., H. 1.

Kelly's Catheter and Kelly's Cystoscope are claimed by Pawlik, formerly of Vienna and now of Prague, as wholly his own devices, and he also claims that Kelly learned the method of catheterizing the female ureter while on a visit to Europe in 1888, never giving the slightest credit to the originator. This statement and claim would seem to call for explanation.

Dacryocystitis.—In a paper in the *Post-Graduate* for November, Dr. A. E. Davis gives the following conclusions: 1. In acute cases, irrigation of the sac with antiseptic solutions along with injections of mild astringents should first be tried. 2. Slit the canaliculus and pass probes. In chronic cases: 1. If the canaliculus has not already been operated on, this should be done at once. 2. Gradual dilatation of the stricture in the nasal duct by Bowman's probes should follow. The larger the probe that can be passed without traumatism to the duct wall, the better. Irrigations and injections may be used in conjunction with probes. 3. If probing fails, the permanent styles are to be tried. 4. As a last resort, destruction of the lachrymal sac. 5. Strict attention should be given to the nose as to examination and treatment in all cases.

Appendectomy.—In the McBurney operation the skin incision is made an inch inside the spine of the ilium in an oblique direction, passing through skin and connective tissue only. The next incision passes through the aponeurosis of the external oblique in such a way as merely to split the fibres and not divide any of them across. The aponeurosis is split a distance of about four inches. The edges of the wound in the aponeuorsis are pulled apart with retractors so as to uncover the surface of the internal oblique, the fibres of which lie at nearly a right angle with the incision made in the external oblique. Then the direction of the incision is changed from nearly vertical to nearly transverse, and the fibres of the internal oblique and transversalis are separated without cutting. When the appendix has been removed, the opening tends to close of itself, as the muscular fibres fall into their natural place.—Elliot, *Boston Medical and Surgical Journal*, No. 18, 1896.

Septicæmia.—Injection of a quart of normal salt solution into the subcutaneous cellular tissue is a treatment which has given excellent results.—LANPHEAR.

Operation in Diabetics.—With our perfected methods we can be more daring, and the writings of Reynier and Léon Legendre demonstrate that diabetics can be as safely operated on as any other class of patients. One point, however, is to be borne in mind—in these cases the risk of "intoxications" is especially great; therefore, it is better not to make use of any antiseptics whatever, but to rely upon rigorous and thorough asepsis.—MARIE.

Œdema of the Kidney.—Boutz gives, in *Vratch*, No. 25, the following indications for treatment: 1. When the œdema increases progressively, extirpation is indicated if the other kidney remains healthy. 2. Preference should be given to the peritoneal procedure. 3. In instances presenting extensive adhesions with neighboring tissues, when the condition of the fellow kidney is suspected and when a large part of the affected organ still performs its function, we must content ourselves with a nephrotomy. 4. This last-named operation should be performed through the lumbar region. 5. In doubtful cases it is permissible to do a protecting nephrotomy. 6. The drainage of the extraperitoneal cavity will be best carried out with the aid of gauze bands. The incision of the anterior abdominal wall is to be completely sutured, and the attempt should be made to suture also the posterior fold of the peritoneum.

Progress of Medical Science.

Need of Uniformity in the Meaning of the Term Still-Born.—Dr. Jesus E. Monjaras, at a meeting of the American Public Health Association at Buffalo, September 15, 1896, suggests the following as an aid to uniformity: 1. That there shall be included under the term "still-born" all children of more than six months of intra-uterine life that are born dead. 2. That there be added to the nomenclature of the causes of death the term that shall represent all children that die within seventy-two hours after birth without known cause, and that they be designated by the term "died at birth without known cause." 3. That the committee on nomenclature of diseases and forms of statistics be authorized to recommend this modification of the existing nomenclature in all the countries of the American continent. 4. That these modifications once adopted in said continent, the same would doubtless be accepted in Europe and elsewhere.

Infantile Scurvy.—Dr. Leidy (*Boston Medical and Surgical Journal*, October 29, 1896) says that infantile scurvy may be defined as a disease characterized by malnutrition, developing insidiously, attended with general debility, anæmia, ecchymoses in various parts of the body (principally the lower extremities and mucous membranes of the mouth), sponginess of the gums (going on to ulceration in severe cases), general muscular weakness amounting to immobility in the lower extremities (going on to pseudo-paralysis), attended with swelling about the joints and excessive tenderness along the lines of the long bones, rarely terminating fatally when early placed under proper treatment. The symptoms vary according to the severity of the attack, etiologically holding an important relation to the deprivation of fresh foods, and almost immediately ameliorated by the administration of a proper diet. This, the so-called therapeutic test becomes of great value in diagnosis.

Should Antiseptic Douches be Given After Labor?—In reply to this question, Dr. Willis writes the following answer in the *Philadelphia Polyclinic:* After a perfectly normal labor conducted under antiseptic precautions in a clean room, the hands of physician and nurse having been perfectly prepared and the patient a healthy woman, one free vaginal douche containing some mild antiseptic agent, such as creolin, lysol, or boric acid, is sufficient, provided the vulva be kept covered with an occlusion dressing. Both the liquor amnii and lochia are in such cases sterile fluids, and infection is not likely to occur except from without, this being prevented by the occlusion dressing. When, however, the labor has been long, forceps have been used, or the physician's hand has been inserted within the uterus for version or removal of the placenta, or considerable laceration of the parts has occurred, an antiseptic douche may be used once a day for five or six days with good effect.

Relation of Alcoholic Indulgence to Insanity.—Drs. H. M. Bannister and Alder Blumer (*American Journal of Insanity*) agree on the following points: 1. Alcoholic excesses produce insanity. 2. They are directly the cause of at least ten or twelve per cent., and probably of a somewhat larger percentage. Indirectly they are among the causal factors of a very large proportion of cases that cannot be directly attributed to alcohol. 3. Moderate drinking is a very indefinite term, and this fact alone makes it impossible to utilize satisfactorily any statistics as to its effect in producing mental disease. There is, however, no reason to believe that moderate indulgence in alcohol is specially conducive to mental health in the average individual; and there is, on the other hand, a certain amount of physiological *a priori* presumption to the contrary. For the victim of hereditary taint or the neurotic, it is undoubtedly often disastrous in its effects in this direction.

A New Sign of Pleural Effusion.—Baccelli (*Il Policlinico*) calls attention to an aid in the diagnosis of fluids in the pleural cavity. The patient utters the word "trentatre" in a whisper. If the fluid is very thin, every letter of the word will be heard; but in proportion as the fluid is thicker the letters are gradually lost, up to final disappearance of all sound conduction. The first letter to disappear is *r*, then *t*, then *n*, and finally the vowel sounds are lost. Direct auscultation in the antero-lateral and inferior regions of the thorax without the stethoscope is required.

Sugar in the Urine.—Dr. N. R. Elliot has devised a new test (*Scientific American Supplement*, October 10, 1896) which he claims is most accurate. It is as follows:

℞ Cupric sulphate ..... gr. xxvij.
Glycerin (pure) ..... ʒ iij.
Distilled water ..... ʒ iiss.
Liquor potassæ ..... ad ʒ iv.

Dissolve the cupric sulphate in glycerin, and heat. When cold, add the liquor potassæ. The second solution is a saturated solution of chemically pure tartaric acid. These solutions are stable and will keep indefinitely. Pour a drachm of the cupric-acid solution into a test tube, and boil gently over a spirit lamp; add two or three drops of the tartaric-acid solution and boil again. Now add the urine slowly, drop by drop, until eight drops are added. If no reaction takes place there is no sugar: but if there is a reaction, yielding a yellowish, or reddish, or greenish-gray deposit of suboxide, and which is marked and unmistakable, sugar is present. The reaction deepens in a few minutes.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

New York, January 23, 1897.

THE SURGICAL TREATMENT OF ADDISON'S DISEASE.

IT is pretty generally agreed that the group of symptoms included in the designation Addison's disease are dependent in some way upon perversion or inhibition of the as yet undiscovered functions of the suprarenal glands. It is highly probable that these organs elaborate an internal secretion, abnormal modification or total cessation of which gives rise to the well-known symptoms of the disease under consideration.

The most common lesion found in fatal cases of Addison's disease is tuberculosis of the suprarenal capsules, although the same lesion may be present in the absence of characteristic symptoms. Other changes in and about these glands have been found less frequently, and occasionally it may be impossible to demonstrate any morbid alteration in them whatever. In this connection it must be borne in mind that alteration in function does not necessarily imply alteration in structure, and it is probable that the view which associates the symptoms of Addison's disease with abnormal or deficient function of the suprarenal glands is the correct one.

The disease is usually fatal, although sometimes deceptive remissions in the symptoms take place, and the duration may be protracted. The treatment has in the past been mainly symptomatic and supportive. Of late, extracts of suprarenal glands have been employed, with reported success in some cases and failure in others. Surgery has hitherto played no part in the treatment of Addison's disease, and it is difficult, from *a-priori* reasoning, to understand what good it is capable of effecting, as in the not unanalogous instance of exophthalmic goitre; but theoretic objections must yield in the face of objective demonstration.

The list of cases of exophthalmic goitre—which may be looked upon as in some respects similar in nature to Addison's disease—in which relief has followed extirpation of the enlarged thyroid gland, is a not inconsiderable one. Additional interest is given this subject by the recent report by Oestreich [1] of a case of Addison's disease, in which the symptoms present disappeared after the removal of a tuberculous suprarenal gland. The case occurred in a woman, fifty-five years old, who was sent to Hadra, of Berlin, to be operated on for carcinoma of the stomach. It appeared that at the age of thirty-three years the patient had been treated for some disease, the diagnosis of which was involved in doubt, although the woman believed it to have been pulmonary tuberculosis complicated by glycosuria. She was subject from time to time to attacks of catarrhal disturbance. For a year there had been progressive muscular weakness, with general debility and great languor, palpitation of the heart, dyspnœa, and swelling of the feet, and there had been loss of weight from ninety-eight to seventy pounds.

The appearance of the emaciated patient was cachectic. On examination, a neoplasm was palpable in the epigastrium, but no other evidence of pronounced gastric disease was present. An old focus of infiltration was found at the apex of the left lung, but no tubercle bacilli could be demonstrated in the sputum. A diagnosis of malignant retroperitoneal glandular tumor was made, and cœliotomy undertaken. On raising the left lobe of the liver and depressing the stomach, a tumor of the size of a small apple was brought into view. This was encapsulated, in color partly white and partly yellowish-brown, and seated upon and to the left of the aorta, with which it pulsated. Assuring himself that the growth was not in immediate anatomic relation with the aorta, Hadra removed the mass and packed the wound with gauze. He was unable to determine the precise relations of the tumor with the abdominal viscera.

The patient recovered happily, with a disappearance of all her previous symptoms, and gained seventeen pounds in weight. Histologic examination of the extirpated structures showed them to consist of a tuberculous suprarenal gland. It would not be fair to doubt the diagnosis in this case, and the relation between the operation and the subsequent result may be reasonably conceded. At all events, the report raises a number of interesting questions, the most important of which is, perhaps, of a therapeutic nature. It may be possible that we have, in extirpation of tuberculous suprarenal glands, a remedial measure in the treatment of some cases of Addison's disease, a conservative measure under any circumstances, and a radical though justifiable one in isolated tuberculosis of those glands.

THE NEW YORK ACADEMY OF MEDICINE, 1847–1897.

THE Academy of Medicine, organized in 1847, is about to celebrate with becoming ceremonies its semi-centennial anniversary. Several of its original members will be present, and addresses will be delivered commemorative of the event. It will be an anniversary of no ordinary significance, both to the citizens of New York and to the medical profession of the city and country. The occasion will also be rendered memorable by the recognition which its importance will receive from the President of the United States, who will honor it not only with his presence but with an address. And the Academy is altogether worthy of the consideration about to be given to its anniversary and the distinction the proposed ceremonies will con-

fer. It came into existence as a conservative force in the profession of this city at a time when the alluring theories of the day were exciting popular interest and seducing some of the younger members from the path of rectitude. At that time the medical profession of this city had no common bond of union, nor was there any method by which the members could be united in an effort to elevate the standard of professional respectability. The call for the first meeting, which was held December 12, 1847, was made by the representatives of the two colleges and the County Medical Society. They stated that "the object is to ask the cooperation of their medical brethren in an undertaking to elevate the character of our profession; to advance its interests and to increase its usefulness by furnishing facilities for social intercourse, promoting harmony among its members, and the means of mutual improvement." One of the older members remarked at this meeting "that the time had come when something must be done to change the character of the profession; that, owing to accidental circumstances, but mainly to the rampancy of quackery, the public had but little confidence in our profession; and that if those members of the profession could be brought together, this confidence might be restored." Another member said, advocating the formation of an academy: "It offered the adequate and only remedy to professional degradation. If a line could be drawn between science and roguery, and recognized among ourselves, the public would soon learn who was upon one side and who upon the other; if this distinction could be made, everything would be done to redeem the profession from the injuries recently inflicted upon it."

No institution of this city has a more honorable record than the Academy. For fifty years it has stood in this community as the exponent of scientific medicine. Its history has been marred by no schisms or lapses from the true faith. With a broad and catholic spirit it has discussed every question which has risen during the last half of the century, affecting the ethical, the public, and the scientific interests of the profession. While tolerant of the diversified views of sincere searchers after truth, it has never been lenient to those who have been enticed into the flowery paths of illegitimate medicine. With unswerving fidelity to the principles delivered to it by its founders, the academy has maintained the honor of the profession at its highest level in the midst of a "wicked and gainsaying generation." In these later days it has become a centre of education, to which the student of medicine, the general practitioner, the specialist, and the author alike resort in the pursuit of knowledge. Its halls are seldom unoccupied by societies devoted to the discussion of the latest discoveries of the science and art of medicine. Nor has the Academy confined its labors to the elevation of its own standard of respectability and to the advancement of its own interests, but with lavish hand it has bestowed the benefits of its labors upon the community in which it has grown to maturity. The health department of New York had its origin in the Academy. The public charities of the city have been constantly moulded into better and higher forms by influences having their power from the same source. In innumerable ways has the Academy exerted a most salutary restraint upon vice and crime, by improving the physical condition of the poor and dependent classes. All honor to the Academy!

THE HEALTH BOARD AND COMPULSORY REPORTS.

The profession of this city will be surprised to learn that the Health Board has finally declared that all cases of pulmonary tuberculosis, public or private, shall be reported to its sanitary bureau, on the plausible ground that the disease in question is pronouncedly dangerous to public health. With every desire to interpret the motives of the Board in the most liberal spirit, the conviction forces itself upon us that the compulsory step taken is a mistaken, untimely, irrational, and unwise one. The medical profession is not yet prepared to endorse the radical measures proposed. While admitting that pulmonary tuberculosis in a very limited degree may be contagious, that the public should be properly educated in regard to the demonstrated causes of infection, that the spitting nuisance should be abolished, and every reasonable means should be used to the end of preventing the spread of the disease, it appears evident that the advisers of the Board have assumed, in the present instance, a position so far in advance of the general opinion of the profession as to the real necessity of the measure that a serious question of authority may be brought to the surface of general discussion. This latter will be a matter to be deplored, inasmuch as the profession has generally, in questions of ordinary policy, seconded any laudable endeavors of the Board to stamp out dangerously infectious diseases. The real strength of the Board depends upon such backing, but when the line is drawn too tightly, when too much authority is assumed, and too many orders are given, a reaction is likely to occur. The argument upon which the action is based is very much one-sided, and calculated, in the interest of a few of the workers in the board, to alarm the public unduly, to place a large number of patients under public jurisdiction, and to inflict unnecessarily extra burdens upon the medical attendant.

The real obnoxiousness of this amendment to the sanitary code is its offensively dictatorial and defiantly compulsory character. It places the Board in the rather equivocal position of dictating to the profession and of creating a suspicion of an extra bid for public applause by unduly magnifying the importance of its bacteriological department. It would be a cause for much regret if such an opinion should take deep root, as it would tend to offset the effects of very much good work already done in the laboratory. We can trust only to time to see how the order will be carried into effect. The objections which will be most naturally raised will be those referring to the personal liberty of the patient, the disposition to superintend the physician in his management of a case, the reflection upon his judgment in assuming that an order is necessary to compel him to exercise the ordinary pre-

cautions against the spread of any disease, and the possibility in the near future of prescribing for his patient according to mandatory rules based solely on bacteriological research. The profession as a whole has watched with jealous eye the encroachments of the Board upon many of the previously well-recognized privileges of the medical attendant, and the order in question is likely in certain quarters to arouse active antagonism rather than to court that cordial support which just now is most needed by all concerned.

THE STATE MEDICAL SOCIETY.

As the date of meeting of the New York State Medical Society approaches, the question must come into the minds of many hundreds of men in and about New York City: "Why should I leave home at this, the busiest season of the year, to spend three days of hotel discomfort in Albany?" As a result of the self-questioning, the decision is usually reached that "the game isn't worth the candle," and the doctor decides to stay at home. There does not seem to be much in these meetings to attract any but the politically inclined practitioner. As an outing with rest, recreation, and friendly intercourse as its chief aim, it would be well enough if the place of meeting offered adequate hotel accommodations. It is most enjoyable and profitable to meet one's "up-the-State" friends, but a man can scarcely sleep three deep and perhaps be made the object of some practical joke in the small hours and keep up the delusion that he is enjoying himself.

As far as the scientific side goes, many men feel disinclined to prepare and read deeply scientific papers before a body whose time limit makes serious discussion almost impossible, feeling that too much of the time is taken up with the politics of the society, which the fact of meeting at the State's capital would seem to foster. Be this as it may, the argument has been advanced that Albany is the only suitable place of meeting because the legislators are there, and to secure their influence and good offices it is better to be on the spot.

It would seem, however, that the committee on legislation ought to be sufficient of itself to impress the law makers in the proper way, whether appointed in Albany, or elsewhere.

Now why not bring the State society to the metropolis once, for a change and by way of experiment? New York is a pleasant place and ought to attract members from all parts. Those who do not care for the proceedings could find ample enjoyment and instruction in visiting the hospitals, the libraries, the theatres, or music halls. All could find hotel quarters to suit the purse and inclination, even if there happened to be a meeting of the Knights of Pythias for the same date.

The William Thorndike Prize.—The committee of the Harvard Medical School to make the award of the William H. Thorndike prize has reported that it found no essay worthy of a prize.

News of the Week.

Medical Society of the State of New York.—The ninety-first annual meeting of this society will be held at Jermain Hall, Albany, commencing at 9:15 A.M., January 26, 1897, and continuing in session until 1 P.M., January 28th. Though the society is composed of duly elected permanent members, delegates, and honorary members, provision is made in the constitution for invited guests. Invitation is therefore extended to all members of county medical societies to attend. On presentation of their names to the committee of arrangements, they will be recommended to the society as invited guests and will have the privilege of presenting papers and taking part in discussions. Reduced fares can be obtained by applying for a certificate at the railway station on starting, which, on endorsement by the secretary of the society and by the special agent of the Trunk Line Association, who will be at the meeting during Tuesday and Wednesday, will entitle to return at one-third fare. The committee on credentials will be at the Kenmore Hotel, Monday evening, January 25th, and members and delegates who arrive then are requested, so far as possible, to register there, or otherwise as early as possible after arrival. Invited guests are requested to register also at the place of meeting. Dr. James D. Spencer is president, and Dr. F. C. Curtis secretary of the society.

Fire at Bellevue Hospital Medical College.—Early on the morning of January 20th a fire broke out in the top story of the Bellevue Hospital Medical College. The dissecting-room floor and part of the floor below were burned. The rest of the building was flooded with water. All the records of the college, however, are safe. The course will not be interrupted, but will be completed in the Carnegie Laboratory and the hospital. The lecture room in the laboratory is large enough. Fortunately, the dissecting for the session has been practically completed. The college building will be promptly restored.

Swine Plague in Oswego County.—As the result of the breaking out in Oswego County of the disease known as swine plague, State Commissioner of Agriculture Charle A. Wieting has caused many hogs that were affected with the disease to be killed. The affected district has been quarantined.

Obituary Notes.—Dr. Asa J. White, of Cortland, N. Y., died January 12th, at his home, of apoplexy. He was born in 1838 in Newfield, Tompkins County, N. Y., and was graduated from the Buffalo Medical College in 1863. He was one year an assistant surgeon of the 109th regiment. A widow and two daughters survive him.—Dr. Thomas T. Janeway, of this city, died suddenly in Bermuda on January 15th. He had been in poor health for several weeks, and had gone to Bermuda the Saturday before, in the hope of recuperating. His death was due to cardiac trouble. He was born thirty-six years ago, and was graduated in medicine from the College of Physicians and Surgeons in this city in 1883. A widow survives him.

Terror in Bombay.—Associated Press dispatches from Bombay state that more than half the population of that city, which has been estimated at nine hundred thousand souls, has fled to escape the plague, and the streets, docks, and bazaars are not recognizable. Business in piece goods, metals, crockery, and hardware is at a standstill. The money lenders have vanished, the courts are deserted, and the judges and officials have gone to a healthier region. Many of the native doctors, graduates of the college, have fled, and those remaining refuse to attend plague cases, or, when they do attend to them, will not touch the sufferers, dreading contagion. The cemeteries are already filled to overflowing, and corpses have even been found in the streets. The nights are made hideous by cymbals and melancholy dirges. Often difficulty is experienced in burying the dead, friends and relations refusing to carry the corpses. In some instances women assisted in carrying them. The official returns show that up to January 13th there had been 3,394 cases of bubonic plague and 2,356 deaths from that disease in Bombay.

Navy Department, Bureau of Medicine and Surgery, Washington, D. C. Changes in the medical corps of the United States navy for the week ending January 16, 1897: January 9th.—Medical Inspector J. C. Wise relieved from duty at the Museum of Hygiene; Medical Inspector J. R. Tryon ordered to examination for promotion, January 11th; Surgeon G. P. Bradley ordered to examination for promotion, January 18th. January 12th.—Surgeon A. C. H. Russell ordered to the *Lancaster*, per steamer of January 27th; Surgeon C. T. Hibbett detached from Norfolk navy-yard, February 1st, and ordered to the *Independence;* Passed Assistant Surgeon F. W. Olcott detached from the *Independence* on reporting of relief, and ordered to the Puget Sound naval station.

A Large Gift to a Hospital.—Mr. J. Pierpont Morgan has offered to build a new home for the New York Lying-in Hospital, now at Second Avenue and Seventeenth Street, to cost $1,000,000, on condition that the society shall raise sufficient money to carry on the work of the hospital on a scale which shall be in accord with the enlarged facilities. In his letter containing this offer, addressed to the president of the hospital, Mr. Morgan says that he has already obtained the plans for the new building, and that as soon as he receives the necessary assurance of support from the governors he will begin the work of construction. It is proposed to erect the new building upon the site of the present one, which is simply an old mansion fitted up for the needs of the hospital.

A Quarantine Against English Ports.—Italy and France have turned the sanitary tables for once on England, and have established a limited quarantine on vessels coming from English and Indian ports on account of the cholera and the bubonic plague, the former on account of the British steamship *Nubia*, which recently arrived at Plymouth with cases of cholera on board, and from which all the troops except a few who are in hospital have been landed. The *Nubia* has been docked in London, and no further cases of serious sickness among her recent passengers have been reported. France now subjects all passengers from Plymouth to five days' inspection. Both countries have issued decrees providing against the possible introduction of the plague. The Hamburg-American Line steamers will touch at Southampton instead of at Plymouth, for the present, on their trips from New York to Hamburg.

Reception to Borneo Explorers.—A reception was tendered on January 14th by the Penn Club of Philadelphia to Drs. W. H. Furness, 3d, and Henry M. Hiller, who have recently returned from an exploring expedition to Borneo after an absence of fourteen months.

A German Surgeon for the Russian Emperor.—Professor v. Bergmann, of Berlin, has been called to St. Petersburg to perform an operation on Tsar Nicholas, who is reported to be suffering from alarming attacks of vertigo. Some years ago, while travelling in Japan, the then Tsarewitch was struck on the head by a native, and it is thought his present trouble may be due to a splinter from the inner table of the skull or a meningeal thickening making pressure on the brain.

The Sale of Bodies.—The investigation into the charges against ex-Morgue Keeper Albert N. White by the commissioners of charity has brought out the fact that the Polyclinic College and Hospital paid $6 for each cadaver received. Realizing as we do how very important it is that graduates in medicine should receive every advantage for perfecting themselves in surgery, it seems too bad that any college should be compelled to resort to such underhand methods of procuring the necessary material. Provision should be made by the city so that no trouble would arise in obtaining cadavers.

Health Officer Doty has recently returned from a trip to Egypt and Italy, where he has been making a study of the shipment of rags from Egypt to this port, in order to satisfy himself as to the efficiency of the disinfection of the same before shipment. He also critically examined the details of the passenger detention at Naples and Genoa. As a result of his visit, he has appointed a resident agent at Suez, who will board all vessels bound here from India, etc., and will communicate at least twice monthly with the quarantine department here. At Naples also a resident physician has been appointed who will personally examine each immigrant passenger and give the steamer's captain a certificate to that effect. This agent will also keep careful track of any outbreak at other Mediterranean ports through his official connections, and will advise the quarantine department here.

An International Conference on the Plague.—The governments of England, France, Germany, Austria, Russia, and Turkey have agreed to hold an international conference, for the purpose of considering precautionary measures against the spread into Europe of the bubonic plague which is raging in India.

J. Hood Wright Memorial Hospital.—Dr. A. Jacobi has resigned from this institution as consulting physician.

Restriction of Medical Practice in Italy.—The Italian Medical Council has petitioned the government to favor a law providing that no foreigner shall practise medicine or be entitled to recover fees unless he has obtained a diploma from one of the Italian universities. At present a foreign qualified physician is permitted to practise among the foreign population, and we believe among the natives as well upon the payment of the legal license fees and taxes.

A Hospital for Consumptive Children on the Riviera.—It is stated that Baroness Hirsch has announced her intention to give 2,000,000 francs ($400,000) to build a hospital for consumptive children on the Riviera.

Legislating for Pure Beer.—It is announced that four bills in the interest of pure beer are soon to be introduced in the legislature, and three of these will aim to fix a standard. One of the bills will be introduced with the approval of the State board of health, and will provide for an appropriation to enable the board to summon the brewers before it during the investigation and from them learn what would be the most desirable standard. Another bill defines pure beer as a beverage made from hops, barley malt, and pure water, and, while permitting the sale of any beverage made from other ingredients which are in themselves not injurious in their effect, will require that they shall be so marked as to indicate whether they are pure beer or whether they are beverages made from rice, corn, glucose, or other substances. A third bill will provide that rice can also be used in addition to the ingredients mentioned in the preceding bill, but no acids. It is claimed that the general demand for light beer makes it necessary for the brewers to use rice. The fourth bill will fix the standard for pure beer the same as that recognized by the German government.

A French Degree for Foreigners.—One may acquire knowledge in France (perhaps), but no one not a native can turn such knowledge to practical account in France, if the French can help it. The Paris University Council is considering the institution of a degree for foreign, and particularly American, students.

Malignant Malaria.—The Russian correspondent of the *British Medical Journal* writes that an epidemic of malaria in malignant form has been ravaging Transcaspia, an Asiatic province of Russia. Letters from Askhabad, the capital of the province, give a harrowing picture of the sufferings of the unfortunate inhabitants of the Merv Oasis, where the epidemic was at its worst. One reads of tents full of unburied corpses or untended sick; fields lying waste and ownerless cattle wandering at will over the country. In Merv itself there was at first an uncontrollable panic, which soon gave way to complete apathy. The whole business of the town and province has long been at a standstill. As even in ordinary years malaria prevails in this region to an extent that would be alarming anywhere else, it is clear that this year the excess must have been very great to create such a state of panic in a seasoned population. Even the cholera epidemic of 1892 which aroused so much fear was a trifling visitation in comparison with the annual tribute of death to the effects of malaria. The cholera attacked only one per cent. of the inhabitants, and caused death to only 0.5 per cent.; while in the same year malaria attacked at least 31.6 per cent. of the population, and caused the death of 5.26 per cent. That was but an average year as regards malaria. But this year these figures will probably be at least doubled, if not tripled. Great credit is given to General Kuropatkin, the governor of Transcaspia, for the measures he has taken to deal with the epidemic. Measures are now being discussed which will aim at the prevention of a repetition of such an epidemic, by preventing a recurrence of the overflow of the large river Murghat in the spring.

Medical Women in London.—Since the admission of women to the London examinations in 1882, more than fifty have taken degrees and many have won gold medals for proficiency in obstetrics, anatomy, and materia medica.

Sugar Coating the Pill.—A pleasing custom exists in a town in Devonshire, England. At Christmas time all the medical men in the place invite those who have been under their professional care during the year, those who are still living at least, to dine with them. After all have eaten at the doctors' expense, the cigars and hot toddy are set out, and then comes the turn of the hosts. Each one corrals his own flock and proceeds to administer a corrective in the shape of a gentle reminder of the indebtedness of each head of the family. The victims are prepared, however, and settle up without demur, and the new year begins properly.

An Active Remedy.—Mr. Preserved Grant and his daughter, Mrs. Ferry, of Chardon, Geauga County, were badly burned October 12th by the explosion of a patent medicine which they were preparing for market. Mrs. Ferry's eyes were blown out, her hands were torn off, and she will probably die, as will also her little daughter. While not withholding sympathy from the afflicted, congratulations are due the public in general for its narrow escape. Probably even the public may appreciate that ignorance which permits careless handling of dangerous chemicals is hardly equipped to minister to the ills of humanity.—*Cleveland Journal of Medicine.*

The State Board of Health of Indiana.—Dr. J. N. Hurty, secretary, writes in explanation of the expression "or other contagious or infectious disease." employed in the circular to which we recently referred: "This is entirely for legal reasons," he writes, "as directed by the attorney-general, in order to make the rule operative in the diseases named. No action at law would stand, unless the ordinance mentioned every known contagious or infectious disease, or adopted the plan of naming the diseases particularly aimed at and following with general terms as we have done."

A Welcome to a Confrère.—A physician named Knöner, living in Schildau, Saxony, published the following advertisement in the local paper as his

greeting to a young physician who had just settled in the place: "One of our citizens has again succeeded in enticing a young medical man to rent his vacant house and set up a practice at Schildau. Although I know that this new practitioner will not be able to maintain himself for long in this town, I have decided not to remain inactive, and therefore declare as under: 1. To all those who avail themselves of the services of the new medical man I shall never again give any future medical aid whatsoever. 2. From October 15th I will allow a discount of fifty per cent. off my bills to any one in Schildau and the neighborhood who asks for it, and I reserve to myself the right to announce a further discount, or to treat my patients gratuitously."

Toronto Branch of the British Medical Association.—It has been determined to revive the Toronto Branch of the British Medical Association, in view of the meeting to be held in Montreal in August next. The branch was organized some years ago, but subsequently lapsed.

The Widow's Might.—A prominent member of Worcester's park commission, who died recently, provided in his will that his body should be taken to Forest Hills Cemetery, and there cremated. His ashes were then to be taken to the summit of a hill in one of the parks, and scattered to the four points of the compass. He is said to have made this provision as a protest against the unnecessary pomp, ceremony, and expense of funerals as they are ordinarily conducted. The wishes of his widow, however, prevailed against the desires of her late husband, and he was buried in the usual manner, after a simple funeral service.—*Boston Medical and Surgical Journal.*

Dr. Grenier, who was recently elected to the French chamber of deputies from Pontarlier, is a practising physician and a Mohammedan. Some years ago he went to Algiers on account of his health and there became converted. He wanted to become a mollah, but as he was lame, and all mollahs must be sound in body, he was told that he could be a "prophet of God" instead, and set up as one in Pontarlier. He dresses in a turban and an Arab burnous, attends to all Mussulman religious duties, practises as a physician without taking fees, gives away all his money in charity, and has made eight converts in the town.

A Protest Against the Indiana Board of Health Circular.—At a meeting of the Shelby County Medical Society held on December 28, 1896, in Shelbyville, the following resolution was adopted: "*Resolved*, That the State board of health, in their recent health circular, No. 5, assailed the dignity of the medical profession, and seriously interfered with its sacred prerogative, by recommending, in their official capacity, a certain preparation, now *sub judice*, and by saying to the physicians of Indiana that they should always and under all circumstances use this preparation in their treatment of diphtheria."

Legislation Against Wheelwomen.—It is proposed to introduce into the Kansas legislature a bill prohibiting the wearing of bloomers by women and making it a misdemeanor for a woman to appear in a public thoroughfare astride a bicycle. The proposer of the bill says eminent physicians agree that these women are ruining their health by riding the bicycle, and that the habit unfits them for the sacred duties of motherhood, and if continued will soon extinguish the race. There is nothing Malthusian about the Kansas Solons, and nothing that threatens to extinguish the race will be permitted if they can help it.

The Dangers of Total Abstinence.—At an inquest recently held in Birmingham, England, the coroner said that when one contemplated the crime and misery resulting from drunkenness it was little wonder that men and women should give themselves up to total abstinence as an example, and unselfishly doing so, he believed, at the risk of their health. He thought that a limited amount of alcohol was desirable at certain periods of life. He was well acquainted with the late Sir B. W. Richardson, and he felt that his life was more or less unselfishly devoted as an example to others and that he would have been benefited by the moderate use of alcohol, having regard to the climate of England and to the work that he did. His total abstinence for twenty years probably shortened his life. This deliverance has naturally excited much indignant comment among the total-abstinence people of the city.

A Russian Horror.—The Moscow correspondent of *The Lancet* relates an almost incredible instance of the hideous results of ignorance and credulity which, he says, is vouched for by an eye witness who writes to a Southern Russian paper. A peasant woman in the village of Slavyansk has a daughter, aged ten years, who recently suffered from some affliction of the eyes. She consulted a "wise woman" in the village, who gave her the following advice. She told her to procure some gunpowder, put it in the child's eyes, and apply a match to it. This advice the mother implicitly followed. The writer of the letter states that he was passing the house at the time, heard the report, and went in to see the cause of it. He found the room full of smoke, and when this had cleared off the wretched child was seen lying in agony with two cavities where once had been eyes. The mother was also injured by the explosion.

The Dignity of Lodge Practice in England.—At a recent meeting of the members of a club corresponding to the "lodges" in this country, the treasurer of the Norwich Medical Institute said their institution had been in existence twenty years, during which time they had so arranged the fees paid to their doctors as to make a profit of between four and five thousand pounds. The doctors grumbled, but if they could do so the members had a perfect right to make a profit out of those they employed. The money had been used to purchase the institute buildings, and had thus benefited the members. Doctors and their friends talked about "crushing the profession," but they had never heard of a doctor employing an assistant, unless with a view to making a profit out of his labor, and why should not a medical institute employing a doc-

tor carry out the same principle? They did not want to fight the medical profession. Physicians should be wise and accept the conditions of service which the clubs, knowing their strength, were determined to exact. The last vacancy they had at Norwich, there were forty-five applicants anxious to accept the post, notwithstanding that the medical papers refused to insert their advertisements. Their consulting physician at Norwich was Sir Peter Eade, who was always willing to be called in when a consultation was desired.—*Medical Times.*

The Bicycle Checks Tuberculosis in Women.—At the last quarterly meeting of the American Statistical Association, Dr. S. W. Abbott, secretary of the Massachusetts board of health, presented some interesting figures regarding the proportion of pulmonary tuberculosis in females to that in males in Massachusetts. The rate in 1851 was 1,451 females to 1,000 males; in 1890, 1,055 females to 1,000 males; and last year, only 974 females to 1,000 males. Last year was the first in the history of the State in which the number of deaths from phthisis in females was smaller than that in males. The fact that a uniform reduction in the rate of female deaths began some five years ago, about the time when women were beginning to ride the bicycle extensively, Dr. Abbott considers significant, and he is inclined to attribute the decrease in the death rate to the great increase in open-air exercise among women which has been inaugurated by the use of the bicycle.—*British Medical and Surgical Journal.*

College of Physicians of Philadelphia.—At a stated meeting of the College of Physicians of Philadelphia on January 6th, Dr. J. M. DaCosta read a paper entitled "Rapidly Developed General Paralysis in Acute Lead Poisoning." He detailed the case of a middle-aged woman who a day or two after sleeping in a freshly painted house manifested motor palsy, more pronounced on the right side and attended with disturbance of speech, headache, numbness and tingling, and increased knee jerks. Though there was neither wrist drop, nor foot drop, nor intestinal colic, a marked blue line was present on the gums and the urine contained lead but was free from albumin. Sensibility was preserved and hysterical symptoms were absent. The heart presented no lesion. Dr. D. D. Stewart exhibited a specimen of a large innominate aneurism cured by the use of gold wires and galvanism, and made some remarks upon the utility of this method of treatment. The patient, who was an unfavorable subject for the operation, being alcoholic and syphilitic and suffering from arterial and renal disease, lived for forty-two months and then died, not from the effects of the aneurism, but from thrombosis of the middle cerebral artery in consequencce of the vascular disease. The aneurismal sac was completely occluded by a firm, organized clot and a second (fusiform) aneurism had formed at the junction of the transverse and descending portions of the arch of the aorta. Dr. J. M. Anders read a memoir of the late Dr. H. Earnest Goodman. Dr. H. A. Hare presented a communication in which he maintained that death occurring as a result of chloroform narcosis was not necessarily due to either respiratory or cardiac failure, but essentially and fundamentally to vasomotor paralysis, as a result of which the subject is bled into his own vessels, the respiration failing from anæmia of the respiratory centre in the medulla and the heart from want of blood. To prevent the accidents of chloroform narcosis it is therefore recommended, in addition to removing the anæsthetic, that the pulse especially be watched and that the inhalation be preceded by hypodermic injection of atropine; and that in case of dangerous symptoms the patient be inverted and compression of the abdomen and chest or bandaging of the extremities be practised. Dr. Alfred Stengel read a paper on the "Value of Auscultatory Percussion in Diagnosis." The election of officers resulted in the selection for a second time of Dr. J. M. Da Costa as *President* and Dr. John Ashhurst, Jr., as *Vice-President.* The remaining officers also were re-elected. Dr. George E. de Schweinitz was elected a councillor and Dr. William H. Wells a fellow.

At a stated meeting of the section on otology and laryngology on January 5th, Dr. E. B. Gleason exhibited a case of leptothrix of the pharynx in which the deposit was dissipated by the local use of hydrogen dioxid, one of cholesteatoma of the external ear, and one of fibroma of the naso-pharynx. Dr. E. Larue Vansant presented a communication entitled "Should Cultures for Bacteriologic Examination be Taken from the Nasal Chambers as Well as from the Throat in Suspected Cases of Diphtheria?" He reported two cases presenting the clinical manifestations of faucial diphtheria, in which, however, examination of cultures from the throat failed to disclose the presence of Klebs-Loeffler bacilli, whereas in cultures from the nasal secretions such bacilli were demonstrable. Dr. Joseph S. Gibb read a paper entitled "Excision of the Tonsils by Means of the Galvano-Cautery Snare," and exhibited the instrument devised by Gradle, of Chicago, by means of which the operation can be performed without loss of blood and expeditiously. Dr. E. B. Gleason detailed a case of extensive fracture of the base of the skull involving the temporal bone, and exhibited the specimen. Dr. B. Alexander Randall demonstrated the brain from a case of recurrent purulent otitis media complicated by cerebellar abscess. The lesion was suspected to be present in the sphenotemporal lobe but trepining in this situation failed to reach the disease. Before a second operation could be undertaken death ensued. Dr. Randall exhibited also a specimen showing extensive destruction of the temporal bone in consequence of middle-ear disease and followed by cerebral abscess; and finally a specimen of mastoid involvement secondary to ear disease.

The American Laryngological, Rhinological, and Otological Society.—The southern section of this society will meet in New Orleans on March 3 and 4, 1897. This will be during the carnival season and half-rate fares may be obtained on the railroads by all intending to take part in the meeting. The chairman is Dr. W. Scheppegrell, New Orleans, and the secretary is Dr. Robert C. Myles, New York.

Reviews and Notices.

HUMAN ANATOMY, GENERAL AND DESCRIPTIVE, FOR THE USE OF STUDENTS. By JOHN CLELAND, M.D., LL.D., D.Sc., F.R.S., Professor of Anatomy, University of Glasgow, and JOHN YULE MACKAY, M.D., C.M., Professor of Anatomy, University College, Dundee. 8vo, pp. 833. New York: The Macmillan Company. London: Macmillan & Co. 1896.

THIS work is a very satisfactory compend of general and descriptive anatomy, in which there are a number of new features referring to a natural system of arrangement and an inductive method of study. The natural dependence of one part upon the other is skilfully brought out and relations of salient and important points are judiciously considered. In the latter respects the work is equally adaptable to the needs of the general practitioner and surgeon. The descriptions are clear and concise, and leave nothing to be desired in the way of simplifying the subjects treated. Many of the time-honored designations for positions, such as anterior, posterior, superior, and inferior, are ignored, and the more proper relations to the planes of the body are considered, thus avoiding much confusion in the minds of the students. The illustrations are quite numerous and consist of photographic representations, carefully prepared wood cuts, and schematic drawings. Nearly half of these are original and are of proportionate value. The histology of the tissues is sufficiently presented to give the student an understanding of the structure of the various organs and the proper dependence of their component parts. The style is admirably adapted to the subject, and the descriptions and explanations take the reader by such easy stages of explanation and demonstration that he loses sight of the study in the pleasure of its profitable progress.

FOODS: THEIR COMPOSITION AND ANALYSIS. A Manual for the Use of Analytical Chemists and Others. By ALEXANDER WYNTER BLYTH. Fourth Edition, Revised and Enlarged. London and New York. 1896.

THIS book, comprising over seven hundred pages, presents the results of the author's experience, besides excerpts from his previous publications. The historical introduction and the careful article on adulteration are the result of considerable labor and research. The scientific portion of the work is well adapted for the professional chemist, for food analyses have been carefully detailed. Chapter III., dealing with starchy and saccharine substances, is very complete. Part IV., dealing with milk, cream, cheese, and butter appears to be the stronghold of this work. It is abundantly illustrated with tables, charts, pictures of apparatus, and also of some infectious micro-organisms.

There seems nothing more to add than to say that the author has given us a very complete work which deserves praise.

NATURWISSENSCHAFTLICHE EINFÜHRUNG IN DIE BAKTERIOLOGIE. Von DR. FERDINAND HUEPPE, Professor der Hygiene in Prag. Wiesbaden: C. N. Kreidel, Verlag. 1896.

THIS book has been dedicated in honor of the one hundredth anniversary of the Friedrich Wilhelm Institute at Berlin. The author reviews certain theories, and elaborates some of his own views concerning bacteriology. He describes disinfection and antiseptics, goes into details about various epidemics, and dwells at length on the historical development of immunization and serum treatment. The book is instructive and written in an attractive manner. Some very good illustrations aid the descriptions of the text.

KLINISCHE PATHOLOGIE DES BLUTES. Von DR. ERNST GRAWITZ. Berlin: Verlag von Otto Euslin, N. W. 6. 1896.

THIS very valuable contribution to medical literature is published as a result of years of clinical experience in the examination of the blood. It is divided into twelve chapters dealing with the morphology, chemical and physiological conditions, anæmic and splenic diseases, poisoning, the blood in gout, diabetes mellitus, hemorrhagic diathesis, the examination of the gastro-enteric blood disorders, pneumonia, asthma; the infectious diseases, and so on.

The book is beautifully illustrated, technique being carefully given. It is evidently the result of great painstaking care and deserves to be carefully studied. It contains over three hundred pages; the type is clear.

A TEXT-BOOK OF HISTOLOGY, DESCRIPTIVE AND PRACTICAL, FOR THE USE OF STUDENTS. By ARTHUR CLARKSON, M.B., C.M., Edinburgh, formerly Demonstrator of Physiology in the Owens College, Manchester; late Demonstrator of Physiology in the Yorkshire College, Leeds. With 174 Original Colored Illustrations. Philadelphia: W. B. Saunders. 1896.

THE student is here furnished with a combined descriptive and practical work, profusely and instructively illustrated with colored plates. Methods have been excluded which have not stood the test of practical experience, and discussions of questions which cannot be settled in a work of this kind have been avoided.

To the student who wishes a really working knowledge of histology, without a history of the subject from its origin and without an account of the numerous controversies upon methods and results, we can commend this handbook. Many of the reagent formulas are from Sterling's "Outlines."

A TEXT-BOOK OF MATERIA MEDICA, THERAPEUTICS, AND PHARMACOLOGY. By GEORGE FRANK BUTLER, PhG., M.D., Professor of Materia Medica and Clinical Medicine in the College of Physicians and Surgeons, Chicago; Professor of Materia Medica and Therapeutics, Northwestern University, Woman's Medical School, etc. Philadelphia: W. B. Saunders. 1896.

THIS work is dedicated to the medical students of the United States, and has been prepared with the view of supplying a permanent reference as well as a preparatory book. Special attention has been given to the pharmaceutical section. Effects due to idiosyncrasy have been separated from those due to toxic action. The unofficinal preparations have received appropriate consideration after the officinal, whenever their properties are known.

The portions included under "Origin" and "Description and Properties" of each drug have been taken almost verbatim from the "United States Pharmacopœia and National Dispensatory." The pronunciation is indicated by prosodial signs according to Foster.

The work naturally contains much valuable information and data. It is a large volume, covering eight hundred and fifty-eight pages, inclusive of clinical and general index. There are inaccuracies, shortcomings, and omissions. Almost every large work of this kind has the same to be said about it. Perhaps they are somewhat more noticeable in the present volume than in some other recent works covering much of the same ground. The weakest part of the work is the therapeutic. Speaking of therapeutics, the author says it is from the Greek word meaning to attend, or serve. Would it not be better to give the student the word itself and let him guess at its being Greek? Considerable Latin is given in the chapter on prescription writing, but, as all medical schools do not yet require a knowledge of this language before admission, it will be useful to most readers.

It seems strange that while the names of François Franck, Reichert, and a number of others are given, in the space devoted to cocaine that of Carl Koller is not mentioned.

Two plate pictures taken from life, or rather from death, of dogs poisoned by strychnine and gelsemium make one sorry for the beasts.

THE MEDICAL RECORD VISITING LIST OR PHYSICIAN'S DIARY FOR 1897. New Revised Edition. New York: William Wood and Company.

THIS year's list contains, besides the usual tables of equivalents, duration of pregnancy; maximum doses of drugs by the mouth and solutions for subcutaneous injection; solutions for atomization and inhalation; emergencies, anti-septics, disinfectants, dentition, etc.

It is arranged for sixty patients per week, with space left for charges, references to ledger page, and special memoranda. The usual departments for consultations, obstetric engagements, vaccinations, deaths, addresses of nurses, and general addresses have been supplied, as well as sufficient room for the cash account. It is bound in red leather, the leaves are gilt edged, and altogether the appearance of the diary is suggestive of the prosperity of the physician on whose desk it may lie.

A Pictorial Atlas of Skin Diseases and Syphilitic Affections. From the Museum of the St. Louis Hospital, Paris. Part V. London: The Rebman Publishing Company, Ltd.

The first plate in this set is one of agminate trichophytic folliculitis, or ringworm of the kerion variety, occupying the back of the neck. Unless told what portion of the anatomy is before one, considerable study is required to make out the part involved. Lupus pernio, or chilblain lupus, must impress the casual observer as being rather overtinted. The disease is an unusual one, and the cyanotic feature of the lesions observed may have been particularly blue.

The coloring of the following plate—one of papulo-tuberculous syphilide—makes, on the other hand, a most favorable impression, because it is the raw-ham color with which one is familiar. The lesions here are pronounced but characteristic. Vacciniform infantile ecthyma and simple infantile ecthyma on one plate, and both included under the designation dermatitis vacciniformis infantilis, form the last subject. The lower of these figures is an excellent representation of the condition, while the upper less-pleasing picture shows a much rarer form of eruption.

Part V. is in keeping with those already noticed, and the descriptive text is well written.

A Manual of Materia Medica and Pharmacology. By David M. Culberth, Ph.G., M.D., Professor of Botany, Materia Medica, and Pharmacognosy in the Maryland College of Pharmacy. Lea Brothers & Co. 1896.

This book "comprises all the organic and inorganic drugs which are and have been official in the United States Pharmacopœia, together with important allied species and useful synthetics, especially designed for students of pharmacy and medicine, as well as for druggists, pharmacists, and physicians."

It is a book of unquestioned value to all for whom it was designed; primarily important to the pharmacist, it is also of use to the physician. For the former we know of no better work of the same character; for the latter it will doubtless prove a stimulus to active-thinking practitioners, not perhaps on account of its pharmaco-dynamics, nor its therapeutics, for in this regard it is of necessity weak, but from the standpoint of its accurate and painstaking accounts of the active constituents of organic drugs.

The large amount of information bearing upon the commercial side of drugs renders the work of especial value to those interested in the collection and importation of medicinal agents.

The book is arranged upon the botanical system of classification, which renders it somewhat unsatisfactory to the average physician, who is, as a rule, untrained to perceive natural affinities in the actions of drugs coming from closely allied families in the botanical sequence.

There are a number of excellent *résumé* tables distributed throughout, and good closing chapters upon "Non-pharmacopœial Organic Compounds and "The Microscope and its Use in Materia Medica." The book is, moreover, well printed and well illustrated.

A System of Surgery. Edited by Frederick Treves, F.R.C.S., Surgeon to London Hospital. Vol. II. 8vo, pp. 1,088. Philadelphia: Lea Brothers & Co. 1896.

The second volume of this work deals with a great variety of topics, with a corresponding distributive authorship, including the admirable contributions of the talented editor. There is manifested great discretion in the systematic arrangements of the subjects and in their concise treatment at the hands of the respective contributors. Not only are the general principles of surgery skilfully applied to ordinary conditions of diseases, but many interesting and striking exceptions are related, which serve to make these discussions consistent, perspicuous, and practical. A leading feature of the work is the large number of illustrations of the varied pathological conditions, which renders it of special clinical value. In all the chapters the aim of the different writers has been to condense the salient principles upon which diagnosis and treatment necessarily depend and to show the bearing of the latter on well-recognized pathological conditions.

While the surgical procedures are sufficiently indicated, there is shown a disposition, especially on the part of the editor, to refer for details and elaborate technique to his operative surgery. This may perhaps be considered quite pardonable in a work of this kind, but the reader will doubtless be ready to forgive all errors in the opposite direction. It is unnecessary to say that the work is in every way an exposition of the present state of surgery from the purely British point of view, and as such must necessarily take its place as a leading authority. All the later methods of operating are duly noted, and the preferences of the writers are clearly presented and the reasons plainly stated. Lengthy discussions on vexed questions are very properly ignored, each writer being content with a conservative view. Thus, in appendicitis, prostatic disease, carcinoma, cerebral tumors, and epilepsy, operations are not invariably indicated, there being a need for still more experience in given directions before positive conclusions can be reached. Altogether the work, so far as it goes, is an admirable digest of the surgery of the day, and a trustworthy guide for the advanced student in search of high authority for conditions and methods.

Essentials of Physical Diagnosis of the Thorax. By Arthur M. Corwin, A.M., M.D., Demonstrator of Physical Diagnosis in Rush Medical College, etc. Second Edition, Revised and Enlarged. Philadelphia: W. B. Saunders. 1896.

The first edition was entitled "Outline of Physical Diagnosis of the Thorax." To this new matter has been added, and alterations have been made which make the little volume more useful. The gist of physical diagnosis is presented in little less than two hundred pages, and is designed especially to meet the wants of students.

The American Academy of Railway Surgeons. Report of the Second Annual Meeting, held at Chicago, Ill., September 25, 26, and 27, 1895. Edited by R. Harvey Reed, M.D., Columbus, O.

The second volume contains over two hundred pages. One is pleased by the manner in which the papers and discussions are presented. The scientific work, with its discussions, is classified into chapters, so that one may readily refer to any particular subject. The academy is doing good work, its motto being "The higher the order of railway surgery the greater the protection to the employee, the passenger, and the company."

The Prescriber's Pharmacopœia: A Synopsis of the More Recent Remedies, Official and Unofficial, with a Therapeutic Index. Third Edition. Kemp & Co., Ltd., Wholesale and Manufacturing Chemists, Bombay. 1896.

This book is simply a reference handbook, and as such is of value. The list of drugs is arranged alphabetically. Under each drug are given its definition, natural order, therapeutic indications, official preparations, doses, incompatibles, and, in cases of poisons, the antidotes. There are also a few pages devoted to urinary testing, which certainly add to the value of the book. The therapeutic index is very complete. The fact that it was compiled by physicians in India adds to its general interest.

Transactions of the American Climatological Association for the Year 1896. Volume XII., containing Part II. of the Report of the Committee on Health Resorts. Philadelphia: Published for the Association. 1896.

This is the report of the thirteenth annual session of the American Climatological Association, held in Lakewood, N. J., May 12, 1896, under the presidency of Dr. James B. Walker, of Philadelphia. It is a neat volume, of nearly three hundred pages, and contains a large number of valuable papers, especially those that relate to consumption and hæmoptysis. The appendix is of great value to the physician-at-large, containing Part II. of the report of the committee on health resorts. The first section of the report is contained in Volume XI., published in 1895. It is an interesting volume, replete with valuable matter, and reflects great credit on members of the association.

Feeding in Early Infancy. By Arthur V. Meigs, M.D. Philadelphia: W. B. Saunders. 1896. Price, 25 cents.

A fifteen-page brochure, being a paper read at the meeting of the Philadelphia County Medical Society, April 8, 1896. A formula for a food is given, which, after fourteen years' experience, the author thinks well of.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON OBSTETRICS AND GYNECOLOGY.

Stated Meeting, December 24, 1896.

SIMON MARX, M.D., CHAIRMAN PRO TEM.

DR. PAUL F. MUNDÉ presented several specimens with the following histories:

"**Dermoid Cyst of Ovary Enucleated from the Uterine Cavity.**—On June 6, 1895, a woman twenty-three years of age, married, mother of two children, who had had one miscarriage one year before, came to my office bringing two bunches of hair in a bottle which she said she had passed per vaginam the day before. She complained of a profuse, highly fetid vaginal discharge. On examination I found the external os widely dilated and protruding from it a tuft of hair, which sprang from the left wall of the uterus within the internal os. There was a deep furrow at this spot, into which I could insert the tip of my finger, and in a few minutes I easily succeeded in enucleating the tumor, which with the tufts of hair I present to the society. The tumor is evidently ovarian, and the only way in which I can explain its presence in the uterine wall is that a dermoid cyst of the left ovary formed between the layers of the left broad ligament, became inflamed and ulcerated through the uterine wall, and protruded into the uterine cavity. I have been unable to find a similar case in literature. That dermoid tumors of the ovary easily become inflamed and suppurate is well known, and there are several cases of perforation of the anterior rectal wall by such a suppurating dermoid, notably one presented by Janvrin to the New York Obstetrical Society some fifteen years ago, in which the dermoid hair protruded from the anus and first called attention to the true nature of the case. My patient's uterus was firmly tamponed with iodoform gauze, and she was referred to Dr. L. J. Ladinski for further observation, who reported an uneventful convalescence.

"**Double Ovarian Abscess, Right Ovary Adherent in Right Iliac Region, Simulating Appendical Abscess.**—A. S——, aged thirty-eight years, mother of two children, was operated on for rectocele on September 26, 1896. At that time there was no evidence of diseased appendages. When ready for discharge, patient suddenly complained of severe pain in the right iliac region. Temperature ran up to 102.6° F., and dulness was evident in the right appendical region. The diagnosis of appendicitis was made and operation advised, but refused. Patient was very obstinate and unruly. Four days later operation was accepted, and at once performed. The usual incision in the right semilunar line revealed an adherent suppurating ovary, which was removed. The vermiform appendix was normal. The fingers passed into the pelvic cavity through the incision detected a large fluctuating and adherent sac in the left half of the pelvis. A second incision was made in the median line and a large intraligamentous pus sac of the left ovary was removed. The wounds were packed with iodoform gauze. Death from exhaustion occurred several days later. Undoubtedly the delay in operating, due to the refusal of the patient, was in a great measure the cause of the unfortunate result. Still the complication of two universally adherent ovarian abscesses was not a favorable condition, although out of thirty or more such subjects on whom I have operated all but two recovered.

"**Myoma Uteri with Appendages, Removed by Cœliotomy; Double Pneumonia; Recovery.**—Mrs. A. R——, aged thirty-nine years, mother of two children. Indication for operation was rapid growth of tumor. Only three silk ligatures were used; the uterus was amputated at the level of the internal os, the cervical mucous membrane was excised and cauterized, and the stump and peritoneal wound were closed by interrupted catgut sutures and buried silk ligatures. Recovery, so far as operation is concerned, would have been uneventful, if a double hypostatic pneumonia and acute gastritis (perhaps caused by the ether and Trendelenburg's position) had not set in twenty-four hours after operation, and jeopardized the patient's life for several days. However, the patient was out of bed on the eighteenth day. This is not the first instance in my experience of pneumonia following ether narcosis.

"**Double Pyosalpinx Removed by Cœliotomy; Attempted Enucleation of Retro-Uterine Intraligamentous Myoma per Vaginam; Vaginal Hysterectomy; Recovery.**—C. W——, twenty-four years of age, no children, was seen at my office in September last with all the physical signs of a large pelvic exudate, with which her history agreed. There was a large boggy tumor behind the uterus, which I suspected would break down and become an abscess. She was sent to her physician with the necessary directions and the request to send her to me again in a month. When she called again as requested, the subacute signs of pelvic inflammation had subsided, but the retro-uterine mass was still unchanged, and I advised operation. After her admission to Mt. Sinai Hospital, I aspirated this mass, expecting to obtain pus, but only clear blood was withdrawn. My first intention was to operate through the vagina, but I finally decided to open the abdomen first, and it was well I did so, for I could scarcely have removed from below the double pyosalpinx I found. The retro-uterine tumor could be plainly outlined and was taken by me to be an intraligamentous hæmatoma. Hence, after closing the abdominal incision, I made a free incision into the posterior vaginal vault. To my surprise, what I took to be a mass of coagulated blood turned out to be a soft myoma, which I proceeded to enucleate. On drawing it out of the vagina I found that the whole uterus was embedded in it. My only course therefore was to remove the whole mass, which I did in the usual manner, using silk ligatures. Both operations were completed in less than three-quarters of an hour. Recovery. This was an error of diagnosis which I am afraid I may repeat in a similar case, for I confess that I see no way of avoiding it.

"**Retro-Uterine Hæmatocele; Ruptured Tubo-Ovarian Sac, Probably Ectopic; Prolapse and Removal of Vermiform Appendix; Accidental Enucleation and Removal of Three Inches of Ureter.**—R. F——, aged thirty years; one child; one miscarriage nine weeks ago; last menstruation three months ago. Retro-uterine elastic tumor. Aspirator showed dark fluid blood. Diagnosis: Pelvic hæmatocele. Free incision in posterior vaginal vault, evacuation of a large quantity of thin dark blood. Left index finger in cavity found it completely closed at the top; on the right side a firmly adherent mass of the size of a mandarin orange, at first thought to be a solid blood clot. It was enucleated without much difficulty with the finger and removed with the volsella. It was at once evident that this was the ovary and tube, filled with a firm coagulum. No ligature was applied. With it was expelled a free strand about three inches long, which was at first taken for the Fallopian tube; and to my surprise and dismay another body rolled out of the vagina which was evidently the vermiform appendix. As it was free and uninjured, I ligated it with catgut, removed it, and returned the stump into the retro-uterine cavity, which was then packed with iodoform

gauze. One week after the operation I was informed that the patient was leaking urine from the vagina. An examination of the specimens was then made by the pathologist, and it was settled without doubt that the smaller cord was the ureter, the larger the vermiform appendix, and the tumor a ruptured tubo-ovarian ectopic sac. An attempt to sound the right ureter (the injured one) through the cystoscope and by touch resulted in the house surgeon, Dr. Luckett, getting the probe in over two inches through the cystoscope, and in myself obtaining the same result by vaginal touch. It was impossible to push the probe farther, in consequence, I suppose, of traumatic and inflammatory contraction of the ureter at that point. I purpose in the near future to attempt to pass a probe into the left (or sound) ureter, and if I succeed in thus establishing beyond question what I do not doubt is the fact, that the right ureter is the injured one, I shall then proceed to consider whether it is worth while to endeavor to stitch together the ends of the ureter, or to implant the upper end into the bladder, or if it is best to remove the right kidney. I fear that the length of ureter missing will scarcely permit its successful plastic restoration or reimplantation, and that the removal of the kidney will be necessary. How I came to tear away the ureter is a mystery to me. In many hundred abdominal and vaginal sections I have never wounded but this one ureter. The same accident happened to Pozzi twice, as I see from the last edition of his text-book just received from him,[1] in enucleating an intraligamentous ovarian cyst and a broad ligament cyst. In the latter case he was eventually compelled to remove the respective kidney; in the former, having discovered the accident at once, he immediately implanted the upper end of the ureter into the bladder with a successful result. The very peculiar coincidence of ruptured tubo-ovarian sac, ureter, and vermiform appendix in a retro-uterine hæmatocele, I can explain only by assuming that the unusually long vermiform appendix hung into the pelvis long before the hæmatocele developed; that the ruptured right ectopic sac became firmly adherent to the right side of Douglas' pouch just over the course of the ureter; that the hæmatocele was closed above by the usual adhesive inflammation of the coils of intestine; and finally that I, in my efforts to dislodge the tumor in the right side of the hæmatocele, ruptured the peritoneum and tore away the ureter, which was firmly adherent to the ectopic sac. No violence was used, nor any cutting instrument; nothing but my left index finger.

"That the vermiform appendix is frequently found in the female pelvis is asserted by Byron Robinson, of Chicago. I do not happen ever to have seen it there before, unless adherent to the right Fallopian tube. Except for the urinary vaginal leakage, the woman is now in perfect health.

"Multiple Hæmatoma of Ovary; Twisted Pedicle; Pregnancy in One Horn of Double Uterus.—B. B——, aged twenty-eight years; last menstruation ten weeks ago. Recent severe pain in right ovarian region; signs of pregnancy. Tender tumor on right side of uterus; sound enters toward left to the depth of three inches. Suspected right tubal pregnancy. Cœliotomy, October 27, 1896. Error in diagnosis; small ovarian tumor on right side with sharply twisted pedicle; double uterus with pregnancy on right side. Tumor removed. Abortion on third day. This is the smallest ovarian tumor with a twisted pedicle which I have seen in quite a number, at least forty, cases of twisted pedicle. Probably there was originally a small polycystic tumor of the right ovary, of the type known as hydrops folliculorum, and the torsion of the pedicle produced an effusion of blood into the follicles, for the tumor was of dark blue color and filled with dark blood.

"Epithelioma of Lip of External Os and Cervical Cavity Removed by High Excision with the Thermo-Cautery.—H. M——, aged thirty-six years, married, no children, bleeding more or less steadily for two months. Excavated ulcer with sharp, undermined border on anterior lip of cervix; clinically undoubtedly malignant. Uterine mobility free; parametria apparently healthy. Hence yesterday high or conical excision of cervix with the thermo-cautery knife after ligation of both uterine arteries with deep silk sutures. The specimen shows how high the disease extends in the cervical cavity, but the division is well beyond the diseased tissue. This is the second case in which I have removed the whole or part of the cancerous uterus with the hot knife. The first case occurred about two months ago. I began with the galvano-cautery knife, the battery being kindly furnished me by the Waite & Bartlett Manufacturing Company, but the platinum was too thin, bent, and finally broke, and I performed the larger part of the operation with the curved Paquelin knife with great ease and rapidity, and with no hemorrhage whatever. The disease in this case involved nearly the whole uterus and extended somewhat into the right broad ligament. When I finished the operation I found that I had removed absolutely all the muscular tissue of the uterus, leaving only a thin shell of the peritoneal envelope, apparently not thicker than the finger of a kid glove. After again thoroughly searing the wound in the broad ligaments, I packed the cavity loosely with iodoform gauze. The patient made a good recovery, the slough separating slowly, and she was discharged in less than a month with the wound perfectly healed, and a fairly long, serviceable vagina. When seen again a month later, everything was healthy. Of course only the future will tell whether the cure is permanent or not.

Inasmuch as in the twenty-seven vaginal hysterectomies for cancer which I have performed (with three deaths) the disease has invariably returned within from two to nine months, I am not enthusiastic in favor of removal of the uterus, wholly or in part, for malignant disease by a cutting operation. It seems to me that Dr. John Byrne is right in his assertion that a slow charring process is the only one by which a thorough removal of the diseased tissue and a destruction of the microscopical cancer germs in the neighborhood of the wound are assured."

Dr. Edebohls expressed the belief that Dr. Mundé's case of dermoid removed from the uterus was originally one of dermoid tumor which developed from the remains of the Wolffian ducts alongside the uterus near the internal os, and from there found its way into the uterine body. The case of injury to the ureter again illustrated the fact that there was greater danger of this accident when operating through the vagina than when operating from above. In connection with the case of double uterus, Dr. Edebohls said he had within a week opened the abdomen of a young woman. She had been married a year, but had never been able to have intercourse properly. The vagina terminated at a distance of one inch above two abdominal tumors, one as large as a goose's egg, the other as large as a hen's egg. Abdominal exploration showed absence of the uterus, presence of one ovary and fimbriated extremity of the tube, absence of the ovary and tube on the other side. He was unable to say what was the nature of the tumors, but thought they were related to the Wolffian ducts.

Tubo-Abdominal Pregnancy; Delivery of a Living Fœtus at the Seventh Month.—Dr. Edward A. Avers presented the uterus and placenta from a case of tubo-abdominal pregnancy. He saw the case in consultation with Dr. Pinckney, and afterward the

[1] Paris, 1897, page 850.

patient was conveyed to the Mothers and Babies' Hospital, where he opened the abdomen. The history pointed to tubal pregnancy of about the seventh month at the time of operation, but the uterus was considerably increased in size and the cervix was soft. Uterine pregnancy was positively excluded on dilating the cervix and removing the lining decidual membrane, which, as he had pointed out on a former occasion, was pathognomonic of extra-uterine pregnancy. On opening the abdomen the fœtal head was found lying between the uterus and pubes. Its weight on delivery was three pounds and four ounces. It lived for some days, and he had hopes of saving it, but death took place from inanition. The placental blood supply was from a few large vessels, given off mostly by the tube; consequently in its removal there was not that amount of hemorrhage which was likely to occur when the vessels were small and numerous, covering a larger area. The amniotic covering of the fœtus had evidently been absent for some time, and the fœtal head was somewhat misshaped from compression between the uterus and pelvic walls, but the normal contour returned before death. The operation lasted three-quarters of an hour; there was considerable shock. The mother died of exhaustion.

The Inguinal Operation for Femoral Hernia.—Dr. George M. Edebohls read the paper. The following were his conclusions: The classical operation from below Poupart's ligament should be the operation of choice for femoral hernia, the inguinal operation being performed only upon special indications. In the absence of such special indications for the performance of the inguinal operation for femoral hernia, the writer would prefer the method of Bassini, modified so that the uppermost sutures would include Poupart's ligament and the periosteum of the os pubis. When the inguinal operation for femoral hernia is indicated, the best method of performing it is to open the anterior wall of the inguinal canal from external to internal ring, hook the spermatic cord or round ligament upward out of the way, and cut through the posterior wall of the inguinal canal. After reduction of the hernia, liberation and high ligation of the sac, and clearing of the femoral canal, the crural ring, if small, should be closed from above by suturing Poupart's ligament to the periosteum of the horizontal ramus of the pubis. Should the hernial aperture be large, a fibro-periosteal flap should be formed and used, in the manner described, to close the crural ring. In either case the irritation of the periosteum produced, tends to new formation, in and about the crural ring, of osseous tissue which will constitute an efficient barrier, efficiently placed, against the recrudescence of a hernia. The saphenous opening may then be closed by sewing the falciform process to the pubic portion of the fascia lata, although this procedure is of secondary importance. The posterior wall of the inguinal canal is reunited by suture, and the inguinal canal reconstructed after the manner of Bassini's operation for the radical cure of inguinal hernia. The chief advantages of the inguinal operation for femoral hernia are the possibility and easy performance of high ligation of the hernial sac, and of high and effective closure of the crural ring. The special indications for the inguinal operation for femoral hernia are: 1. The coexistence of complete or incomplete inguinal hernia with a femoral hernia of the same side. 2. In women, the coexistence with femoral hernia of a retrodisplacement of the uterus which can be corrected by shortening the round ligaments.

Dr. W. B. DeGarmo said he had expected the author would favor the inguinal operation for femoral hernia in nearly every case. The paper, however, showed that their views were not far apart. Dr. DeGarmo had operated in twenty-three cases of femoral hernia, twenty-one in women, two in men, during the last six years. In all the operation was done from below. In one instance the inguinal canal was opened for inguinal hernia, and he thought of operating from that direction for the femoral hernia, but lack of familiarity with the method deterred him from undertaking it. On another occasion he would hope to try it, with the aid of Dr. Edebohls. He had used but one method, which was original with himself, but which he thought was also probably original with many others. It consisted in cutting down over the sac, loosening the neck of the sac well up under Poupart's ligament before opening it, then opening it and treating its contents in any way which might be deemed advisable. Then traction was made upon the sac, and it was ligated as high as possible, cut off, and the stump replaced within Poupart's ligament. With three exceptions he had used silk ligatures altogether. In suturing, he began as near the femoral vessels as possible, passed down to the pubic bone, and included all the tissues. Three, sometimes four sutures were passed, the last one quite close to the attachment of Poupart's ligament to the pubic bone. Most of his patients had been seen in his private practice, and if there had been recurrences he would probably have heard from them. He knew of recurrence in only two cases.

PRACTITIONERS' SOCIETY OF NEW YORK.

Stated Meeting, December 4, 1896.

Andrew H. Smith, M.D., President, in the Chair.

Superheated Dry-Air Treatment of Stiff and Painful Joints.—Dr. Virgil P. Gibney demonstrated superheated dry-air treatment of stiff and painful joints, and afterward read a paper on the subject (see p. 109).

Malgaigne's Operation on the Lower Lip.—Dr. Charles McBurney presented a man on whom he had operated two weeks before for epithelioma involving a large part of the lower lip, necessitating removal of nearly the full breadth of the lip as the base of the triangle, the apex extending down on the chin. He showed the patient to illustrate the advantages of the Malgaigne operation for closing in this large gap. By carrying the incision from the angle of the mouth out on the cheek and down only to the mucous membrane, dissecting this up, and making another incision at a lower level, one was able to bring the edges of the wound together and cover the inner surface of the skin which had been brought forward with the dissected mucous membrane in such a manner as to leave no deformity and scarcely a perceptible scar. By varying the line of the incisions somewhat, one could as successfully close the gap when removal of the whole lip required making a rectangular instead of a triangular wound. In spite of the evident advantages of this method, it seemed to be little practised by surgeons.

Amputation with Periosteal Flap in Lower Third of the Leg.—Dr. Joseph D. Bryant presented an illustrative case of amputation with periosteal flap in the lower third of the leg, according to a method which he had practised in more than a dozen cases in this locality. The flap was made a little longer than a fourth of the circumference of the limb at the point of amputation, and included the periosteum attached to, not dissected from, the soft parts. In suturing the flap no stitches were put into the periosteal portion, this being simply folded over the end of the bone. The advantage of the method lay in the fact that it gave a freely movable and painless stump, which al-

lowed the patient to wear an artificial limb with comfort. Some of the fourteen patients whose legs had been amputated in the lower third in this manner had worn an artificial limb within a month after the operation. In the case presented, the operation was done for necrosis of the tibia. A diagram was shown of the condition found at autopsy in the first case which he had operated upon in this manner, the patient having subsequently died of malignant disease. What little cicatrix which the method of operating had left had become almost entirely absorbed.

THE NEW YORK PATHOLOGICAL SOCIETY.

Stated Meeting, October 28, 1896.

JOHN SLADE ELY, M.D., PRESIDENT.

Colloid Carcinoma of Stomach and Omentum.—DR. F. L. JEFFRIES presented a specimen from a case of colloid carcinoma of stomach and omentum. The patient, a man, forty-eight years of age, had enjoyed good health up to two months prior to his admission to the hospital, on September 17, 1896. At that time he began to suffer from persistent nausea and vomiting, and the abdomen was observed to be larger than usual. While in the hospital he complained of headache and shortness of breath, and had a short, dry cough. He died on September 26th. At the autopsy the entire peritoneum was found to be covered with small nodules. These nodules involved the peritoneum covering the diaphragm, the mesentery, and even extended down into the pelvic cavity. The liver, spleen, and pancreas were normal. About three-fourths of the wall of the stomach were thickened with this same growth, which apparently had its origin in the pylorus. Both the lungs were quite adherent to the diaphragm. Microscopical examination proved the nodules to be colloid carcinoma.

Carcinoma of Pancreas and Liver.—Dr. Jeffries then presented specimens from a case of carcinoma of pancreas and liver. The patient, a laborer, forty-eight years of age, was admitted to hospital on September 12, 1896. His health had been excellent up to about three months before, when he began to experience pain in the right hypochondriac region. This was soon followed by enlargement of the abdomen and considerable loss of flesh and strength. On admission, the patient was very weak and the skin was dry and yellowish. There was no cough or expectoration, and the heart and lungs were normal. The abdomen was distended with fluid. The lower border of the liver could hardly be felt. The urine was yellow. The clinical diagnosis was carcinoma of the liver. At the autopsy, the right lung was found to contain many white nodules, varying in size from that of a pinhead to that of a pea. There were a few such nodules in the other lung. The liver contained many white nodules, varying in size from that of a marble to that of a fist. The largest one was at the free border above the gall bladder. The gall bladder contained one large gall stone and two small ones. An impacted gall stone, half an inch in diameter, was found in the cystic duct. There was a large nodule in the head of the pancreas. The spleen and intestines were normal. The kidneys were much congested. The pancreas seemed to have been the first organ involved.

Perforation of the Stomach.—Dr. Jeffries also exhibited specimens from a third case, the history of which was unfortunately very meagre. The patient, a German, about thirty-five years of age, had been admitted to the Trinity Hospital on October 23, 1896, and had died on October 26th. It was stated that on October 18th he was suddenly seized with severe abdominal pain. On his admission a diagnosis of appendicitis had been made, and an exploratory operation performed, but the latter had failed to disclose any appendicitis or reveal the true condition. The autopsy showed a general peritonitis, and also peritoneal adhesions uniting the liver to the diaphragm. On separating these adhesions a cavity was discovered, the floor of which was formed by the stomach and half of the upper surface of the liver. The cavity was lined with considerable exudation, apparently indicating that the process was older than would appear from the history. There was also a perforation into the stomach, but the opening was round and smooth, and there was little evidence of inflammation there. The interesting question was as to the length of time that this had existed, and whether such a thick capsule as constituted the wall of this cavity could have been formed in seven days.

Discussion.—THE PRESIDENT referred to a similar case presented to the society a year or two ago, in which there was about the same thickening and involvement of the stomach, but in which the carcinomatous condition had been confined to the stomach.

DR. MARY PUTNAM JACOBI thought that the history and appearances of the case just presented agreed fairly well with those of a typical round ulcer of the stomach, with perforation and localized peritonitis. Microscopical examination of the tissues around the perforation might be interesting, as possibly disclosing thromboses and explaining the nature of the perforation. The first acute attack of pain probably coincided with the occurrence of the perforation. Such adhesions, she thought, could form in seven days.

THE PRESIDENT was of the opinion that the only way to settle the question about the capsule would be to determine by microscopical examination just how much old connective tissue was present.

Giant Cells and their Mode of Formation.—DR. CHARLES A. VALADIER exhibited under the microscope a section from a giant cell sarcoma of the tibia. It had been taken from one of the specimens in the laboratory of the College of Physicians and Surgeons, and was presented because it exhibited some interesting features of giant cells. In some places these giant cells seemed to show protoplasmic processes, and at other places retractions of the protoplasmic mass looking like pseudostomata. He had concluded that they were in the act of embodying some of the surrounding sarcoma, and further study of the specimen seemed to confirm this view. On looking up the literature, he had found that the question of the origin of giant cells and their significance in a tumor were much disputed. The fact of phagocytic action was mentioned by one or two observers, but more especially in regard to foreign particles rather than microorganisms. Two interesting experiments were mentioned in Virchow's *Archiv*, of giant cells found not only in tumors, but also in normal granulation tissue in wounds. They had been produced experimentally by placing small pieces of cotton, catgut, and hair under the skin of animals. After a short time, the granulation tissue which grew around these exhibited giant cells, and these cells had such phagocytic action that they not only embodied in their mass certain portions of hairs but also the pigment of the hairs. The other experiment consisted in placing two small pieces of cover glass with a capillary space between them, in the omentum of a frog. Here giant cells also developed. The author believed that the inflammatory process set up by these foreign bodies drew to the parts leucocytes, and the welding of two or more of these leucocytes caused the development of giant cells possessing phagocytic action. Dr. Valadier said that he had seen these giant cells in

epitheliomata and sarcomata. Their presence in sarcomata had been explained as having been occasioned by the osteoclast, but on this point there was much difference of opinion. He would like to raise these questions, viz.: Are these cells, as shown in the specimen, due to irritation within the tumor, as, for instance, from the presence of pigment? May not the giant cells obtain their nuclei from the phagocytic action of these pseudopods?

Dr. J. S. Thacher said that he had found giant cells so frequently present in various inflammatory processes, particularly when there were small pieces of foreign matter, such as bits of sponge and dressings, that in the laboratory they had come to speak of these as "foreign-body giant cells," in contradistinction to those found in tuberculosis. He had come to believe that giant cells were produced by irritations of various kinds; they were sometimes very abundant in a simple surgical wound. They usually differed from the giant cells of tuberculosis in that the latter had their nuclei arranged peripherally and had a necrotic centre.

Dr. George P. Biggs said that he had also observed giant cells very commonly, but those apparently of purely inflammatory origin were usually somewhat smaller than the true giant cells—they might be perhaps better described as multinuclear cells.

Dr. Thacher replied that the cells he had referred to were certainly as large as the cells usually described as true giant cells.

Dr. Louis Waldstein said that the more one observed giant cells under different conditions, the more one became impressed with the fact that they might have different origins. Those that he had seen in tuberculosis of glandular structures, such as the testicle and the kidney, had given the impression of being the product of a necrobiotic process—a fusion of cells which had gradually lost their distinct individuality. Then again, there were other giant cells, such as in the sarcomata and other neoplasms, which gave the impression of the body of the cell being still alive—as if there were multiplication of nuclei. Again, one was struck by the fact in tuberculosis, as well as in the cases referred to by Dr. Thacher and Dr. Biggs, that the bacilli were found inside of the giant cells. One might be led to suppose that here also the giant cell had had a phagocytic action. The cursory examination that he had made of the specimen presented by Dr. Valadier hardly allowed of the expression of a definite opinion, but he was in doubt as to the presence of true pseudopods. The empty space around the cells was probably due to the hardening process to which the tissue had been subjected. He would be inclined to assume that the form of the cell depended upon the contraction resulting from the dehydration of those cells.

Dr. Valadier said that it had been suggested to him that these spaces might have resulted in the way just mentioned by the last speaker. If this were so, the sarcoma cells should not follow the same outline—the dehydration would hardly have the same effect on the cells and on the tumor.

The President said that the giant cells of sarcoma, syphilis, and tuberculosis had a different origin. The last two were the result of a necrobiotic process, as Dr. Waldstein had said. In 1887, the tubercle bacilli had been described in the interior of the giant cells of tuberculosis, and at this time a phagocytic action had been attributed to these cells, but it had seemed to him quite as likely that the giant cell resulted from the massing together of a number of the epithelioid cells of a tubercle. These giant cells were formed at the point where the poison which produces cheesy degeneration was most abundant. These became fused together, there was a drawing in of the nearest epithelioid cells to the mass, which gradually underwent a similar degeneration, and so the giant cell spread. In this way might be explained: (1) The frequent occurrence of tubercle bacilli in the centres of giant cells; (2) that the cheesy matter was usually in the centre of the giant cells in tuberculosis; and (3) the peripheral arrangement of the nuclei. There did not seem to be any doubt that the giant cells in tuberculosis were derived from the epithelioid cells, and not from any chance leucocytes. Another point strengthening this idea was the distribution of the nuclei at one end of the giant cell. In the sarcomata the matter was totally different; it was strikingly suggestive of the myeloplaques of bone marrow, and of the osteoclast. Moreover, we found these cells almost without exception in those sarcomata which had their origin in bone. If the giant cell in this form of sarcoma were the analogue of the osteoclast, then we might very properly attribute to it a phagocytic action. What the function of the myeloplaques were he did not know.

Dr. Waldstein thought they were always found where calcareous matter had been destroyed, so that it was after all somewhat analogous to the other form of degeneration already referred to. The typical giant cell did not always have the nuclei at one end—they might be around the entire periphery, and in many cases it was possible to demonstrate that the giant cell did not originate in epithelial cells alone, even in tuberculosis, but from epithelial cells.

Abscess of Kidney; Cystitis without Symptoms.—Dr. Martha Wollstein presented specimens taken from a married woman, twenty-nine years of age, who had been a patient in the New York Infirmary for Women and Children. The woman had had two children. The first symptoms of her last illness developed one week after the second confinement, and four months before her death. After exposure to cold, the feet and ankles began to swell, and one week later anorexia, diarrhœa, and vomiting were present. The œdema then spread very rapidly, and soon culminated in a general anasarca. After three weeks of treatment in the hospital the œdema all disappeared. The youngest child died shortly after this, and the mother's symptoms almost immediately returned, probably as a result of exposure to cold. There were symptoms indicative of pneumonia—a temperature of 101° F., respirations 36, pulse 120, although during the month she was in the infirmary the temperature did not exceed 100° F. The œdema was the most marked symptom, and was quite general. There was fluid in the peritoneal and pleural cavities. The urine was pale, had a specific gravity of 1.018, and contained much albumin and some leucocytes, with epithelial and granular casts. There was no uræmia. At the autopsy it was found that the pleural cavities contained about three pints of fluid. There was no pleurisy. There were some red hepatization in the right lower lobe and marked œdema of both. The heart was practically normal. There was a typical nutmeg liver. A large quantity of fluid was found in the peritoneal cavity. The spleen was soft, friable, and congested. The stomach and intestines were normal. The right kidney showed the typical appearance of the large white kidney. In the upper part was a depressed yellowish cicatrix measuring about half an inch. The left kidney was very adherent, and it was much smaller than the right. Only about one-third of the organ was true kidney tissue, the remaining portion having been converted into cheesy matter. This was stained for tubercle bacilli, but none were found. Both ureters were patent. The bladder showed chronic cystitis, especially around the trigone. The uterus was normal, and in a state of hyperinvolution. The tubes and ovaries were normal.

The interesting points in the case were: (1) The absence of symptoms of cystitis throughout the entire illness; (2) the relative age of the lesions; and (3) the absolute age of both lesions.

Dr. Mary Putnam Jacobi said that in view of the cystitis it was possible that the abscess of the kidney might have been due to an ascending process from the bladder, prior to the last confinement. She thought that this was the case, and that it explained why the overworked right kidney had been so susceptible to cold. It was unfortunate that no examination of the ureters had been made during life. The absence of pus in the urine would seem to show that nothing had been discharged from the left kidney for a long time.

Endotheliomata or Epitheliomata of the Neck.—Dr. George P. Biggs presented specimens taken from a man, seventy years of age, who five months before coming under observation had first noticed a small lump beneath the right side of the lower jaw. This had grown steadily, but had caused no pain until a few weeks before coming under observation. Another lump had developed at a corresponding point on the opposite side of the neck a few days before his admission. Both tumors were removed. The first one measured 5 by 4 by 3½ cm.; the second, 4 by 3 by 2½ cm. That on the right side had caused some ulceration of the skin by the tension produced. Both tumors were circumscribed, but not distinctly encapsulated. Attached to each one of the tumors was some submaxillary gland tissue. Both tumors were quite firm, and on section presented a grayish granular appearance, with scattered yellowish points. They resembled in gross appearance rather an epitheliomatous growth than a connective-tissue growth. The gross and microscopical appearances of these tumors, and of the one next to be presented, were the same.

Specimens were also presented from a man, forty-six years of age, who eight months prior to coming under observation had first noticed a small growth on the right side of the neck, near the angle of the jaw. This had grown steadily in size until, on admission, it extended from the thyroid cartilage in front to the posterior border of the sterno-mastoid muscle behind, and from the cricoid cartilage below up to a point behind the lower jaw. It completely surrounded the internal jugular vein, so that a portion of this vein was resected at the operation. The mass measured 5 by 5 by 2½ cm., and was accompanied by several enlarged lymphatic glands. In these were circumscribed areas of distinct tumor tissue. Microscopically, all these tumors presented circumscribed areas of cells, which appeared to have developed in some pre-existing channels. The cells were arranged in concentric layers, those most central being larger and epithelioid in appearance, while the middle and outer layers were smaller and ovoid. At the periphery of the lobules a regular row of cells formed a sharp outline. A few very small pearl-like bodies, such as were present in endotheliomata, were seen. In the central portion the cells were more or less degenerated. He was disposed to consider these growths identical with several recently described as endotheliomata, but he would like an expression of opinion on this point.

Submaxillary Tumor; Mucoid Degeneration.—Dr. Biggs also presented a tumor removed from a boy fourteen years of age, who had first noticed the growth under the angle of the jaw two years and a half before coming under observation. It was situated very close to but was apparently not connected with the parotid gland. It measured 3 by 2 by 1 cm., and was irregular in outline. Some portions appeared to consist entirely of viscid, transparent mucus. Microscopical examination showed that a considerable proportion of the tumor had undergone mucoid degeneration, but in certain parts were ovoid spaces, lined and filled with cells which were of epithelial type and not much degenerated. It was impossible to determine the origin of the tumor, but possible sources seemed to be an outlying portion of parotid gland, or one of the fœtal ducts of the neck.

Dr. Thacher said that the specimens presented by Dr. Biggs reminded him of a dermoid cyst over the coccyx which he had examined. The lining wall of the cyst had been made up of cells having a very similar size and shape. He thought that the tumor presented might be an endothelioma of branchial origin.

The President said that possibly the last tumor presented might have been a portion of the parotid gland, which had become entirely separated from the main portion of the gland and had become converted into a retention cyst.

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

NEW-YEAR HONORS FOR DOCTORS — MANCHESTER INFIRMARY—EDINBURGH JOURNALS—SENTENCE ON A QUACK—OYSTERS—ST. GEORGE'S HOSPITAL—THE DAIRY—FARADAY LABORATORIES—THE PARKE STATUE —MRS. GARRETT-ANDERSON—THE LATE SIR GEORGE B. OWENS.

London, January 1, 1897.

At last the "powers that be" have consented to honor the profession by calling one of its distinguished members to the upper house. In the list of New-Year honors for 1897 conferred by the Queen there is a peerage for Sir Joseph Lister. For many years there has been a feeling that the profession has been treated badly in the matter of honors. There was a great expectation at one time that Sir B. Brodie would receive a peerage, but obstacles seemed to have been made, and ever since more or less discontent has been expressed at intervals with the neglect or disregard of medical men in high quarters. No doubt very few are wealthy enough to accept a peerage. On the other hand, there are not a few who by their scientific and medical knowledge would be able to give most valuable counsel in this age of sanitary progress. In the House of Commons the few doctors who have obtained seats have been useful; but the more dignified upper house should afford a more suitable sphere for men who have devoted themselves to medicine. Science is well represented in Lord Kelvin, and Sir Joseph Lister, who is president of the Royal Society, will be an excellent medical peer.

Dr. Douglas Powell, who is physician extraordinary to the Queen, receives a baronetcy. Dr. Kynsey, inspector-general of hospitals in Ceylon, receives a knighthood; and Deputy Surgeon-General Mosse, superintendent medical officer of Jamaica, a C.M.G.

The conservative ministry is to be congratulated on opening the doors of the senate to doctors, who in all other countries have long been recognized as proper recipients of national honors. This government might well follow up its initiative by a free distribution of baronetcies and knighthoods among distinguished physicians and surgeons.

A poll of the trustees of the Royal Infirmary, Manchester, has been taken as to whether it shall be rebuilt on the present site or a more suitable one be sought for. Out of 853 voting-papers returned, a majority of 46 appeared in favor of the present site. It seems, however, that 496 trustees did not vote, and it is thought that the poll taken will hardly justify proceeding to expend £200,000 on a site that is acknowledged to be unsuitable. Manchester is wealthy

and her citizens are liberal. It is therefore to be expected that the question at issue will not be settled merely with regard to expense. The best scheme and the best site ought to be obtained.

From this date Edinburgh is to have two medical journals. I should have thought one enough, but Scotchmen know their own business. The *Edinburgh Medical Journal*, with which we are familiar, dates from 1855, when it was formed by the union of two others, and thus has a pedigree going back to 1805. Recently a new publisher acquired the property, and a movement was made to establish another, the proprietary of which should be professional. I hope the rivals will preserve the Scottish dignity. The multiplicity of journals at the present day is of no little inconvenience to those whose time is fairly occupied. That Scottish medicine was not in absolute need of additional journal accommodation appears to me evident from the fact that London men have been admitted to pad out the table of contents.

The quack who called himself "Dr. Ferdinand" and the "World's Fair physician," has been condemned to twelve months' hard labor. Not, however, for practising and promising to cure cancer, nor even for his frauds; but for perjury, in connection with the death of a victim. It was proved at the trial that this rascal was a plumber, who was many years ago convicted of stealing. Afterward he started as a cancer curer, and declared he was "M.D., U. S. A." When examined by the coroner about this bogus degree, he said he had studied for it in America: but it was proved that he was in business as plumber and glazier at the time he swore he was in America studying at an eclectic college for this degree. It would be a good thing if the persons who sell bogus documents of this kind could be brought to book. Cannot the United States suppress this traffic?

The danger of eating raw oysters has received another illustration. The medical officer of health for Marylebone has met with cases of diarrhœa and of typhoid fever which, he tells us in his report, he has traced to the consumption of raw oysters.

The Duke of Cambridge presided at the opening of the new operating-theatre of St. George's Hospital last week.

The Prince of Wales opened the Davy-Faraday Research Laboratories last week. These have been presented to the Royal Institution by Dr. L. Mond, together with a handsome sum as an endowment. Dr. Mond told a very distinguished audience that he had named his gift after the two men who had carried on much of their work on the spot now occupied by this building. The prince expressed the gratitude due from the nation to Dr. Mond, and felicitated him on naming the laboratories after the two greatest professors of the institution. Lord Rayleigh and Professor Dewar have undertaken the direction of the new laboratories without remuneration. They are the present professors of physics and chemistry to the Royal Institution.

Field-Marshal Lord Roberts, at present commander-in-chief in Ireland, unveiled the statue of Surgeon-Major Parke in Dublin, on the 19th ult. The memorial is in front of the Royal Dublin Society's museum. Lord Roberts expressed the greatest admiration of the late officer and pride that he was a fellow-countryman. He found it difficult to realize how much Surgeon-Major Parke had accomplished in so short a life—only thirty-eight years. Parke is represented in his working African costume, bare headed, and his hands resting on his rifle.

Mrs. Garrett-Anderson, M.D., has been elected president of one of the branches of the British Medical Association. The fear expressed by some members when it was first proposed to admit ladies as members, that the annual meeting might be presided over by one of them, may be nearer of realization than was then thought possible.

The death is announced of Sir George B. Owens, M.D., at the ripe age of eighty-eight. He took his first diploma in 1832, settled in Dublin in 1845, and graduated M.D. (Glasgow) in 1850. He was lord mayor of Dublin in 1876, and later was sheriff. As a poor-law guardian and chairman of the Southern City Dispensary he did good work, and was universally esteemed by his professional brethren and by Dublin society.

OUR PARIS LETTER.

(From our Special Correspondent.)

OPENING OF THE NEW YEAR—HEALTH OF PARIS—DEATH RATE BELOW THE AVERAGE—THE THOMSON CASE—ABORTION AND UNJUSTIFIABLE OVARIOTOMY—LOOSE GYNECOLOGICAL CLINICS—GOVERNMENTAL ACTION TO REGULATE PRIVATE HOSPITALS AND CLINICS—PASTEUR'S REMAINS LAID TO REST IN THE INSTITUT—NEW REMEDIES—PARIS NIGHT SERVICE—PROF. LABORDE'S NEW INSTRUMENT.

PARIS, January 4, 1897.

THE first days of the new year have been ushered in by a slight increase in diseases of the respiratory organs, but mostly not serious—colds, bronchitis, laryngitis, and mild cases of grippe predominating.

The service of municipal statistics has issued its weekly bulletin, showing that the mortality rate during the week that has just ended is nine hundred and fifty-one, or a little inferior to the average, nine hundred and sixty, at this season of the year. The health of Paris is therefore satisfactory.

The professors and general practitioners have returned from their Christmas and New Year's holidays, the École de Médecine has opened its doors again, and medical Paris is in full swing once more.

Since the lamentable *affaire Thomson*, in which the government claims, first, that criminal abortion was committed, and then unjustifiable removal of the uterus and ovaries—for which offence two well-known Parisian doctors are now in prison and will be tried shortly—official attention has been directed to the numerous *maisons de santé*, private hospitals, and policlinics, more especially those devoted to gynecology—as it was in one of these that Miss Thomson died in consequence of the operations.

The present legislation in this regard is quite insufficient, and the representatives of the State and municipality are consequently unable to exercise an efficient control of the institutions in question. It will therefore be necessary to apply to the Chamber of Deputies. What is wanted is a new law, in accordance with which the opening and functioning of private clinics shall be surrounded by serious legal guarantees. As above noted, it is more especially against the gynecological clinics that the measures are called for. There are in Paris not only establishments where abortion and unjustifiable ovariotomy are performed, but others where eyes are unnecessarily sacrificed. Before authorizing the opening of a private clinic or hospital, the prefect of police should ask for and obtain the favorable report of a medical commission—composed, for example, of the dean of the Faculty of Medicine, of the president of the Medical Society of the hospitals, of the president of the Society of Surgery, and two physicians of the benevolent offices. Furthermore, a service of supervision, administratively organized in conditions analogous to that of insane asylums, would also be charged with looking after such clinics and institutions permanently, as regards hygiene and antisepsis.

One point, however, and a very important one, seems to be entirely overlooked, and that is professional secrecy. And no one can tell in what measure and what fashion this would be interfered with, nor how much the free exercise of a liberal profession would be touched in the premises.

It is only establishments of doubtful character that would fear legal control; those of the best class would welcome it, as obtaining thereby a recognized official standing, which some of them have not at present.

On Saturday last the mortal remains of the great Pasteur were solemnly transferred from the Cathedral of Notre Dame to the Institut Pasteur, and there laid in their final resting-place, the crypt, above the vault of which are cut the simple words, "*Ici repose Pasteur.*" Among those who took part in the ceremony were representatives of the worlds of science, literature, art, medicine, law, theology, philosophy, etc. The following paragraph from the discourse of Mr. Tissié, president of the Association of Students, is quite characteristic and gives the keynote of all the others: "The institut that Pasteur has founded is not only the temple of a science that has not failed in one of its promises, but also a school of generosity where our youth can come to seek the most noble inspirations. We have not forgotten the words that Pasteur addressed us on one of our fête days: 'Young men,' he said, 'whatever may be your careers, never let yourselves be attainted by disparaging and sterile scepticism; live in the serene peace of the laboratories and libraries; work until the moment that you will have the immense happiness of thinking that you have contributed something to the progress and good of humanity.' Dear and venerated master, your benevolent voice will never repeat to us again these encouragements, but your memory and your eternal work remain with us, to remind us through struggles, through faintings and calumnies, that we should be faithful to that ideal which was yours—the alleviation of human suffering."

Each of the four English delegates—Sir Joseph Lister, Sir W. Priestley, Sir John Evans, and Sir Dyce Duckworth—then mounted the tribune in turn and expressed all the admiration, respect, and sympathy of the learned men and societies in England, of which they were the representatives. After this, the ceremonies closed and Pasteur was left alone in his glory. The crypt, which is behind a large grating of wrought iron, is entered by descending nine marble steps, and is encrusted with golden mosaics, the arches resting upon four groups of columns (three in each) of porphyry—one red between two green, with white capitals in the Byzantine style. Within we see Faith, Hope, and Charity; on the walls, the vine and hops, in memory of Pasteur's work in the fermentation of wine and beer; then there are the sheep preserved from foot rot and leg sore, the chickens cured of cholera, and further on the dogs, rabbits, and the docile guinea pigs, that are so often sacrificed in the laboratory and that are here honored as if they were collaborators.

A fitting tomb for Pasteur, and on the field of his labors—in the very midst of all that contributed to his greatness.

The new compound anilipyrin, obtained from exalgin and antipyrin, is destined to rival both drugs as an antipyretic and analgesic. It is a whitish powder, to be given in doses of from twenty-five to fifty centigrams, or from five to ten grains.

Another new compound is that of quinine and naphthol β, producing chemically a double monosulphate. This body consists of yellow rhomboid prisms, having a bitter taste, insoluble in cold water, soluble in hot water and alcohol. Acids do not decompose this body, that thus reaches the intestine in the same state in which it is taken by the mouth. It is only in presence of an alkali that it separates itself into its two components, which are very active under these conditions; the quinine possessing, in addition to its antithermic properties, a considerable bactericide power, destroying completely microbic life in a twenty-per-cent. solution. The dose is 0.50 centigram, three, four, five, or six (maximum) times a day. It is best given in wafers. It has already been given with brilliant results in typhoid fever, intestinal tuberculosis, and dysentery.

This "chinaphthol, as it has been christened, presents an analogy with asaprol, which is the double sulphate of lime and naphthol β, and on this account was employed with great success by Dr. Blind in acute articular rheumatism. The chemical combination owes its existence to Professor Riegler, and is likely to prove a valuable addition to our therapeutics.

In spite of the recent organization of the night medical service of Paris by the prefecture of police, grave abuses have arisen therein; for instance, the bills are very high, and some of the physicians had arranged with their clients to put down a call made during the day as a night visit. In consequence of this and other irregularities, it has been decided to establish a fixed fee which will not be modified. This service will be in force from ten o'clock at night until seven o'clock in the morning. Persons needing a physician or midwife between those hours, have only to go or send to the commissary of police, and an agent will conduct them to the doctor and afterward accompany them home.

A propos of the Institut Pasteur, the Baroness Hirsch, widow of the celebrated Vienna banker, has just given the sum of two millions of francs. It seems that not only are the daily treatments at the institut given in public charity to rich and poor alike, but savants like Dr. Roux and Professor Grancher are paid little or nothing for rendering such great services to humanity. Moreover, Dr. Metchnikof gives every day an open lecture to seventy or eighty students, who have to pay not one centime for matriculation or inscription of any sort. Thanks to this handsome donation, the Institut Pasteur will be provided with new and additional chemical and biological laboratories, which will make it the most complete institution of its kind in the world.

Professor Bouchard is continuing his interesting work and experiments with the radiograph. By making use of currents of very high tension he has been able to obtain sparks forty centimetres in length, causing the organs of the thorax to appear in detail on the phosphorescent screen. The organs within the abdominal cavity have not yet been seen so distinctly; in fact, nothing beyond the arch of the liver and the pale space of the stomach when the latter is extremely distended by gas.

Professor Laborde, whose discovery that rhythmic traction of the tongue would induce respiratory movements of the lungs quicker and more surely than any other method known to science in cases of asphyxia from whatever cause, has invented a new instrument, a combination of the microphone and phonograph, which will undoubtedly have as great practical value in cases of deafness as it has scientific interest. He exhibited it at the last meeting of the Academy of Medicine, at which also Professor Panas made a very conclusive communication on the treatment of extreme myopia by ablation of the crystalline. The operation, which is really efficacious, is the more indicated the younger the subject. Of course, the operation should be resorted to only in those cases of exceptional myopia in which the near-sightedness is greatly accentuated or such that work is impossible or very much impeded.

ICE BAGS FROM BICYCLE TIRES.

To the Editor of the Medical Record

Sir: Recently having occasion to apply an ice bag to a limited area of the face, and not being near a supply house, I had the patient's husband make a bag from a section of an old inner tube of a bicycle tire. One end was sealed with bicycle cement and after the cracked ice was put in the other end was folded over and encircled by a cord. This plan could be used in making ice bags for the face, mastoid, larynx, spine, groin, or in fact for any part where the application of ice to a limited area is desired. Again is "the bicycle in therapeutics" in evidence. G. H. Stover, M.D.

Eaton, Col.

LET US ABOLISH "APPENDICITIS"!

To the Editor of the Medical Record.

Sir: In venturing to make a proposition regarding the nomenclature of the inflammatory affections of the vermiform appendix, my motive is the desire to eliminate the constantly recurring irritation caused to the reader by the common use in medical literature of certain philological monstrosities. I refer not only to the familiar "appendicitis," but also to "appendectomy" and "appendicectomy." Who is responsible for the term "appendicitis" I do not know nor do I care. But so much is certain, that the reckless ease with which the word was coined cannot be excused by the difficulty or impossibility of finding a better, more rational, less barbaric, and yet intelligible expression.

In the case, for instance, of the inflammation of the Descemetian membrane, known under the form of "descemetitis," the selection of this barbaric noun can be excused by our inability to invent a better one. Widely different from this is the case of the vermiform appendix. There is ample, good, and sufficiently plastic material in the normal and customary terms of Greek anatomical nomenclature that could have been utilized in a legitimate manner for attaining correct and precise expression. The Greek term for the vermiform appendix, transliterated in Latin script, is *apophysis scolecoides—apophysis* standing for appendix, and *scolecoides* for worm-like or vermiform. A good word can be coined either from *apophysis* or from the nominal root of the adjective *scolecoides*, which is *scolex* (*Anglice*, worm). The former would be "apophysitis;" the latter, "scolecitis."

I would discard "apophysitis," however, on account of its phonetic similarity to "epiphysitis," which might lead to misunderstandings. "Scolecitis," on the other hand, is unobjectionable. It is brief, easily remembered and pronounced, tersely expressing the meaning sought for; and though the word *scolex* occurs in the nomenclature of helminths—denoting the undeveloped form of ecchinococcus—it is met with nowhere else in pathology, and, once accepted, would carry a single and well-understood significance.

The therapeutic derivatives of the pathological term follow in a natural and unconstrained manner. Cutting for the exposure of the appendix would be scolecotomy; an operation involving its removal, scolecectomy.

In making these simple and, as it seems to me, rational propositions, I count upon the judicious and weighty approbation of the Medical Record, whose efforts on behalf of the upholding of linguistic purity and good taste are well remembered and much appreciated by all its readers.

Let cacophonic "appendicitis" and atrocious "appendicecotomy" be forever abolished, and let us have instead euphonic "scolecitis," "scolecotomy," and "scolecectomy." Arpad G. Gerster, M.D.

New York, January 16, 1897.

CONGENITAL TEETH.

To the Editor of the Medical Record.

Sir: I have read with much interest the contributions by Dr. E. S. McKee, of Cincinnati, and Dr. A. S. Waiss, of New Orleans, on congenital incisors.

From the time of the deformed Richard to the present, this condition has been looked upon as an ill omen, and the midwives inform us that a child so born is sure to die within a few months.

I hope to be able to prove the contrary. On January 12th last my wife gave birth to a nine-pound girl baby—our first. The child was well developed and normal in every way with the exception of having two lower incisors. Within two months these teeth turned black and seemed about to decay, but never became loose. After a time they cleared up and now look like ordinary teeth. She began to walk at ten months and is now, at a little more than eleven months, well nourished, weighing twenty-two pounds, and runs all about the house. She has recently cut one upper incisor.

These cases are interesting, and I would like to know if there are ever more than the two usual sets of teeth, or will these congenital teeth be the ordinary temporary set? J. Q. Allen, M.D.

Montrose, Col.

CONTAGIOUSNESS OF LEPROSY.

To the Editor of the Medical Record.

Sir: The action of the New York County Medical Society, in passing unanimously the report of its committee against the segregation of the lepers in New York City is something astounding. There are only three individuals isolated at North Brother Island, but the number of lepers, foreigners, coming and going, according to competent authority, amounts to about a hundred. These are loose on the streets of New York, with or without the knowledge of the competent authorities.

The reports says that "the disease is probably infectious." Well, is not that enough to show the necessity of isolation?

No one doubts that leprosy is inoculable; it must be, if it is a bacillary disease.

Dr. Petersen, professor of dermatology and syphilis in the University of St. Petersburg, is of opinion: 1. That leprosy is a bacillary disease, communicated by means of contact, though it is probable that for the further development of the bacilli a certain individual predisposition is necessary, as is the case with the micro-organisms the cultivation of which will often only succeed upon certain means of nourishment. 2. Since it is possible for leprosy to be communicated from man to man, we should erect colonies for the lepers, where isolation and the prevention of propagation can be secured.

Dr. Petersen, as president of the commission appointed by the Russian government to inquire into the conditions of leprosy in his country, and to devise the best means for the treatment of the patients, is about to report to his government in the sense above noted.

Dr. Dehio, professor of dermatology and syphilis at Dorpat, says that "the discovery of the bacillus has convinced medical men that the disease is contagious, and that by actual contact, not through the air, water, or food. The predisposing causes are misery, poverty, and dirt." He quotes numerous cases which prove contagion. He says "the incubation period of the disease is generally from two to three years, but has been known to last from ten to fifteen years, which accounts for contagion being so seldom detected."

Dr. Bergmann, lecturer on dermatology, of Riga, believes that leprosy is spread by contagion only.

Dr. Reissner, of the Riga Leper Asylum, is of the same opinion.

Professor Unna even goes so far as to oppose the discharge of anæsthetic cases—that is, of such as show no bacilli.

Arming is a contagionist.

Munro, late of St. Kitts, West Indies, is the pioneer of compulsory isolation.

Patrick Manson says that leprosy is contagious, but that the disease, introduced into the system, will grow only in persons susceptible to it.

Professor Sousa Martens, of the San José Leper Hospital of Lisbon, says that in his opinion the increase of leprosy in Portugal is probably due to the fact that the law enforcing segregation is now obsolete. He believes in contagion.

Dr. Panixo Munox, of the Seville (Spain) Leper Asylum, believes that leprosy is contagious.

Dr. Roberto Campana, of the Bacteriological Institute of Rome, believes also in contagion.

Dr. Rogers Pasha, director-general of hospitals and health officers, Cairo, Egypt, considers leprosy a contagious disease.

Dr. Engle Bey says that, although he does not believe that the leper bacillus is the cause of the disease, he is convinced that leprosy is contagious.

Goldschmidt, of Madeira, is a pronounced contagionist, although he thinks that misery and dirt do the work generally credited to the bacillus.

Smirnhoff, of Helsingfors, Finland, is a contagionist.

Professor Saltzman, the director-general of Finland, does not want lepers to be treated in the same wards with other patients. He thinks they are more dangerous than syphilitics.

Sederholm, the highest authority on leprosy in Sweden, believes that even anæsthetic lepers may spread the contagion in the first stage. He says that leprosy has diminished in Sweden only in those districts where hospitals have been built.

Hansen and all his assistants believe that leprosy is contagious. So do Kaurin, of the Reknas Leper Asylum at Molde; Holmboe, chief medical officer of Norway; Professor Boeck, of Christiania; Dr. Sand, of the Trondhjem Leper Asylum; and Dr. Borthen, the leper eye specialist of Norway.

Impey, of Cape Town, South Africa, is a confirmed isolationist. So are all the Sandwich Island physicians.

Carrasquilla, of Colombia, declares that the increase of leper cases in Colombia, from four hundred to twenty-seven hundred in forty years, is due to contagion and non-isolation.

Robelin, of Cuba, has published a pamphlet with the title, "Is Leprosy Contagious or is It Not?"[1] He concludes that it is contagious. I find in this pamphlet the following quotation. By way of winding up my tale, I shall give it in its entirety.

"The following conclusions are taken from the last and quite recent study of Neisser:[2]

"1. The lepra bacillus is the cause of all leprous affections, every time when its mode of propagation is unknown.

"2. All the observations concerning heredity or family disease are rightly interpreted as cases of infection in the family.

"3. The possibility of direct contagion is undoubted, from the moment when the bacilli of the diseased individual reach the surface of the body (cutaneous ulcers, etc.). However, the danger and the probability of infection is very slight, as the introduction of the bacillus into a healthy man meets many difficulties. The latter may be connected with certain individual conditions (absence of predisposition), or on the properties of the bacillus itself (necessity of a development tranquil and without disturbance of the infected point, etc.).

"4. The existence of spore, or, better, of stable forms, admits the contagious nature of leprosy. This contagion may be direct, from individual to individual; it may be indirect, as, for instance, by means of deposits of infectious matters in the ground (corpses), or of an accidental contact through aliments, drinking-water, etc.

"The multiplication of the bacillus outside of the human organism is not likely to occur. The attempts at cultivation show that animal heat is necessary for the development of the bacilli. So far, man is the principal agent of the leprous virus, and there is no reason for protesting in the name of humanity against the isolation of lepers.

"5. The individuals who come in close contact with lepers, as by marriage, etc., do not become lepers.

"The contrary is proved, as we have seen. Even supposing this to be the case, would it prove that leprosy is not contagious? What should we, then, say of tuberculosis? Marital tuberculosis is exceedingly rare, as Leubet (of Rouen) demonstrated in 1884. Will it be said that tuberculosis is not contagious? We shall not insist. Consequences must be wrong if founded on wrong premises.

"6. Individuals in contact with lepers—as physicians, sisters of mercy, assistants, etc.—do not contract leprosy.

"This is very hackneyed and beyond serious argument; it would be time to drop it forever. Absence of contagion in hospital is a negative argument, as has been shown by Danielssen himself. The same might be said of tuberculosis. In a number of diseases the same thing happens. How many physicians, assistants, etc., attend syphilitics, tinoses, and tuberculous patients without contracting these affections. Are they less contagious on that account? Leubet himself has just shown, in the Academy of Sciences in Paris, that the transmission of tuberculosis in hospitals is very rare. Would it be reasonable to conclude that tuberculosis is not contagious? Such arguments ought to have no place in modern studies. What we have just said is founded on good logic. Besides, we can quote cases where assistants of lepers have been infected. Read the works of Schilling, Landré, the cases of MacNamara, Hildebrand, Robertson, Livingstone, Carter, Pasquier. Dr. Robertson quotes a case.[1] Dr. Vidal published the case of a Brazilian physician, who, attending a patient, became a leper. Why should we quote more facts? What has been said covers the case.

"7. The lepers residing in places exempt of lepra do not transmit the disease to those within their surroundings.

"This is absolutely unacceptable. What happened in the United States? The American dermatologists say that imported leprosy is not confined to the individuals, but is transmitted to healthy Americans and sons of healthy individuals. It is often said that the sixty or one hundred lepers who live in Paris do not propagate the disease. To this we answer that the incubation of leprosy extends over a large period, and to judge with certainty we ought to wait a long time. Erasmus Wilson, who considered the importation of lepers into London as very dangerous, said that it was necessary to wait. But why should we quote only European localities? Is it not proved that leprosy did not exist in America before it was imported? It is proved that such countries as have had no intercourse with lepers have not acquired the disease. To all

[1] "Es O no Contagiosa La Lepra?" Por el Dr. D. Enrique Robelin, Habana, 1887.

[2] "Histologische und bacteriologische Lepra-Untersuchungen."

[1] Lancet, 1867.

these reasons is added a modern and absolute proof—the epidemic of the Sandwich Islands. This fact alone, in the absence of all others, would be more than sufficient to prove the contagion of leprosy."

ALBERT S. ASHMEAD, M.D.

NEW YORK, December 29, 1896.

"LEPROSY" OF THE BIBLE.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: Replying to Dr. Porter's letter concerning "What Moses Knew about Leprosy," I would say that the disease described by Moses and termed "leprosy" in King James' version of the Scriptures, is clearly not the affection known by this name to-day. In fact, we do not know of any existing disease corresponding to the one mentioned by the Hebrew law giver. The word "leprosy" occurs also in the same version of the New Testament. Here, however, the matter is a little clearer, for if we turn to the Greek version, and compare it with the writings of the Greek physicians, we will see the disease referred to was the one now commonly known under the name of psoriasis.

HENRY G. PIFFARD, M.D.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending January 16, 1897:

	Cases.	Deaths.
Tuberculosis	182	111
Typhoid fever	15	5
Scarlet fever	148	6
Cerebro-spinal meningitis	2	4
Measles	165	6
Diphtheria	283	27
Laryngeal diphtheria (croup)	12	7
Chicken-pox	32	0

The Vienna Academy of Sciences has just opened a contest with a prize of 10,000 florins for the best work on ultra-violet light. The decision will be made in 1899.

Dangers of Aconitine.—In one instance a fifth of a milligram of the crystallized azotate of aconitine produced pronounced manifestations of intoxication by the drug—dilated pupils, creepy feelings, cramps, feeble respiration, arrhythmic heart beat, pricking of tongue and lips, constriction of the throat, abundant flow of saliva, excitation alternating with prostration, and finally complete arrest of respiration. By means of artificial respiration, injections of ether, tincture of belladonna, and frictions with mustard water, etc., recovery was brought about. The advice is given in employing this drug never to order more than a tenth of a milligram.—DR. TONDEUR, *Concours Médical.*

"Monatsblatt" is the title of a new, or rather resurrected journal published in German, and intended for apothecaries, druggists, and physicians. An attack upon the School of Pharmacy, a poem, and the advertisements are in English. It would scarcely seem necessary at the present day to publish such journals in any but the English language. All druggists and practising physicians should read the language of their adopted country, and to maintain medical societies whose transactions are conducted in a foreign tongue and medical journals published in a foreign language seems un-American and not for the best interests of the profession as a whole.

Beer Yeast in Diabetes.—At first a strict regimen is insisted upon; then two of the following powders are to be taken daily, until the sugar disappears:

℞ Antipyrin	0.50
Cinchona	0.40
Tannin	0.10

After this a teaspoonful of beer yeast is given before each meal and continued for a long time.—BOULLAND.

Roentgen Rays in Cancer.—The case treated by Dr. Despeigne resulted fatally, but there had been noted a pronounced diminution in volume of the tumor under the influence of the rays, the general state of the patient was improved, and the pain ceased. It is thought that perhaps if applied early it might have some decided influence upon malignant growths.—*Journ. d'Accouchements.*

Pyrogallol Poisoning.—In an instance related by Vollmar a ten-per-cent. ointment applied to a patient aged sixty-nine years brought about marked symptoms of intoxication, although the region and time of application were both limited. Locally there were produced œdema and dermatitis, while the general symptoms included fever, prostration, and albuminuria.

Measles in Cambridge, in an epidemic form, is reported.

Cuban Physicians.—According to the *Bulletin Méd.*, of November 11th, there has been issued an appeal to the Spanish government for more physicians. There is said to be a great scarcity of physicians in Cuba. A movement was recently inaugurated by the physicians of St. Paul to raise money to buy medicines, etc. A committee, consisting of Drs. Kelly, Wheaton, and Boeckmann, has already raised several hundred dollars. It is expected that the supplies and medicines will be sent under protection of the Red Cross Society, as no articles contraband of war will be sent.

Small-Pox and Yellow Fever in Cuba.—Dr. D. M. Burgess, U.S.M.H.S., in his recent report, states that during the week ending December 17th there were 306 deaths in Havana, 57 of these caused by small-pox, with about 500 new cases; and 55 caused by yellow fever, with 150 new cases. Fifty-two of the 55 deaths from yellow fever were among Spanish soldiers.

The Germ of Yellow Fever.—A dispatch sent from Rome to a London publication states that Dr. Gaccarelli has discovered the germ of yellow fever. So many scientific researches have been made in Italy which have borne fruit that we can only hope that the above report will be productive of something more definite.

A Delicate Compliment is paid the recipients of a circular sent out this week by a lady who advertises her newly established maternity home. The good name of the institution is asserted in the following retro-active manner: "The respectability and professional standing of those physicians who I believe will be my patrons will soon prove to be the guarantee of the character of my home."

Infected Milk.—The investigations of the health board extending into the annexed district have shown that more than sixteen per cent. of the cows are unfit for milk production. Over twenty thousand persons in this city are supplied with milk from city-kept cows.

MUCOUS COLITIS, A FUNCTIONAL NEUROSIS.[1]

By W. MENDELSON, M.D.,

NEW YORK.

By the terms mucous colitis, mucous colic, membranous enteritis, diarrhœa tubularis, colonic dyspepsia, pellicular enteritis, pseudo-membranous enteritis, fibrinous diarrhœa, hypochondriasis pituitosa, and a host of other synonyms, there has been known for some three hundred years a complex of symptoms which deserves to be more generally recognized by the profession at large than it is. Though, according to Woodward,[2] it was first described as far back as 1554 by Femelius, and though from time to time admirable articles upon it have appeared in the medical journals, yet, as far as my observation goes, the knowledge of its existence, or at least the recognition of its importance, has not become the general property of the profession. Not that the condition is a rare one. On the contrary, if looked for, it will be found to exist in various grades of severity in many patients who are under treatment for "general debility," "neurasthenia," "chronic dyspepsia," "catarrh of the bowels," and other similar vague troubles; and its recognition will often afford the key to the true understanding of these vexatious cases.

In this paper, I do not propose to give an exhaustive account of the trouble in question, but I shall confine myself chiefly to my own observations, and shall develop the nature of the disease as I have conceived it.

Symptoms.—In the symptomatology of this affection there are three cardinal symptoms, which, if looked for, will not be found wanting, and which are so characteristic as to be pathognomonic. These three cardinal symptoms are: Neurasthenia, mucous passages, abdominal pain.

The symptoms are not all present to the same degree nor all at the same time. Any one or any two will usually predominate; and any one may be so slight as scarcely to attract attention. Another highly characteristic feature of this affection which must strike the observer is its marked chronicity—for few patients come to you for treatment who have not had the disease for months at least, while many have been suffering for ten years, for fifteen years, or even longer. This very chronicity is a point in diagnosis, allowing you to throw out most if not all of the organic diseases of the intestine.

Of the three symptoms which I have called cardinal, I have placed the nervous one first, because I believe it to be the essential and basic factor in the disease, and, being so, the one whose importance must be given particular consideration in formulating a rational conception of the trouble, and, consequently, of a rational form of treatment. For not only has neurasthenia, in its various protean manifestations, never been absent in any of the cases of mucous colitis which have come under my observation, but I believe that the reverse of the proposition may almost as confidently be affirmed—namely, that if neurasthenic patients be closely questioned, very few will be found who have not had at some time repeated characteristic passages of stringy mucus, associated with abdominal pain.

While, in my opinion, the neurasthenia is the most exponential of the symptoms, it is usually not the most prominent. For it is the second of the cardinal symptoms—the passages of mucus (together with the associated pain)—that usually causes the patient to seek the physician's aid.

This mucus may be passed daily for a period of days, weeks, or months; or there may be a discharge for a few days, then a varying period of freedom, after which the mucous discharges begin again. In my own cases I have noticed that the discharge almost always occurred in the early morning,[1] the subsequent movements being generally free from mucus.

The attacks of mucous colitis are usually brought on by some nervous strain, as hearing some bad news, worrying, a fatiguing journey—in fact, by anything depressing, mentally or physically. The movements themselves may present a variety of types, but in most cases incline toward the diarrhœal. They may be of normal consistency, or quite hard, or of a watery or pasty nature. Sometimes the first movement will be normal, followed shortly by a loose one containing the mucus, or several loose movements may follow several hours after the first and normal movement.

The mucus is usually in the form of flat or round cords, from one-fourth to three-fourths of an inch in breadth, and often a foot or more in length. These are very often taken for worms by the patient. The mucus may also appear in flakes, or as shreds and patches, or in the form of tubular casts of the intestine, or in the shape of round masses, varying from the size of boiled sago grains (which they much resemble) to lumps as big—as I once saw—as a mandarin orange, the latter giving rise to excruciating pain as it passed the rectum.

The mucus is translucent or opaque, is grayish-white or yellowish in color. Its consistency varies from that of a thin jelly to that of an elastic, tenacious, and sometimes rather tough gelatinous mass. A characteristic feature is that the mucus is never intimately mixed with the movement, as in an acute colitis, but that it can always be seen lying apart from the fæces. Thus, when there is constipation the fæcal masses may be coated with the mucus, or jelly-like blobs of it may be seen adhering to them; while, if the movement be loose, the whitish, ropy masses, often looking like worms, can easily be seen as being quite apart from the fæcal mass.

Examined with the microscope, the mucous masses are seen to consist of a structureless, gelatinous ma-

[1] In his article on "Morning Diarrhœa," Delafield (New York Medical Record, May 11, 1895) has described cases which seem to be of the kind commonly classed as mucous colitis.

terial, sometimes faintly fibrillated, and containing scattered epithelial cells, bits of undigested food, and other forms of intestinal débris. Occasionally I have observed streaks of blood. Andrew Clark has observed upon the surface of the mucus the impress of the mouths of the intestinal follicles.

Passing now to the third cardinal symptom—the abdominal pain—we will find that the pain varies from a dull aching to the most severe colic. In my cases, as already observed, it has usually come on early in the morning, before daylight, rousing the patient from sleep and hurrying her to the watercloset, when, after one or more movements, the pain subsides and allows the patient to sleep again. Other patients will complain of colicky pains, often very severe, during most of the forenoon and persisting often for a long while after the bowels have moved.[2] It is rare, in my experience, to find the pain persisting till the afternoon or evening, and this is probably because the offending mucus has been evacuated during the earlier part of the day.

In the case of the patient already referred to, who passed a mass of mucus the size of a small orange, the tenesmus was most agonizing, and she compared the preceding pains in severity to those of labor. As regards the physical signs which may be observed in this affection, they are limited to finding painful spots on palpating the abdomen. These are usually along the course of the transverse and descending colon, less often over the ascending colon. The pain produced by pressure is seldom acute, and the patient can usually indicate beforehand just where the sensitive spots will be found.

Diagnosis.—If the association of the three cardinal symptoms—neurasthenia, mucous passages, and abdominal pain—together with their chronicity, be kept in mind, the diagnosis is readily made. And yet few cases will come under the physician's care without a history of having been treated for a variety of diseases, so little, as I have before observed, does the recognition of this condition seem to have been absorbed into the common stock of medical knowledge.

The most usual error is to regard it either as a true inflammatory disease of the intestine—either a catarrhal enteritis or an ulceration—or to look upon it as a form of intestinal dyspepsia, the nervous symptoms (really primary) being held to be secondary.

I well remember the case which first called my attention to the subject. The patient, a lady, had been under treatment for ten years by her father, a very intelligent physician and a man well read. He had treated her for the diarrhœa in every variety of way, and when he finally turned her over to me he expressed the fear that she had tuberculous ulcers, as she had emaciated considerably for the two preceding years. Probably if the neurasthenic symptoms had not been so marked as they were in her case, and the case altogether so striking a one, I, too, would have fallen into the same error and would not have framed in my mind the conception of the trouble which I finally did. For it was not until I began to see more of these cases, and looked through the literature of the subject, that I found that that which at the time seemed to me like a discovery had all been well described years ago, and that, too, over and over again. So much for personal reminiscence.

There is one possible source of error which I ought perhaps to mention, though it is hardly likely really to mislead any but a careless observer. It is this: Occasionally those neurasthenics who are constantly watching their stools will bring to you what they regard as portions of the lining of the bowel itself. When these are not mucus, they consist of some undigested portions of food. In this way I once saw a large membranous sheet, which on microscopic examination proved to be the aponeurosis from a piece of meat. And only recently a hypochondriac brought to me, in great alarm, a tubular structure, which proved to be the outer woody skin of an asparagus stalk, the soft inner portion having been digested away.

Etiology.—As for the cause of the malady, I have perhaps already dwelt sufficiently upon its neurotic etiology. It is not a disease of servant girls nor yet of truck drivers; but of sensitive, highly strung, overanxious, overburdened mothers, or of hysterical young girls, and of overworked, hypochondriacal business men, who seldom take a vacation and who no longer know how to enjoy one when they do take it.

Sex and Age.—As women furnish the bulk of our nervous patients, so they, too, are more often sufferers from mucous colitis than men. Young girls are occasionally affected, and even children[1] are not wholly exempt, as I have had one occasion to witness. It is rare to observe the disease in a woman who has passed the menopause, a period when nervous excitability becomes markedly lessened; and old age in both sexes, I believe, is practically if not wholly exempt. It is the ages from, say, twenty to forty or forty-five—that is, the child-bearing period of woman—which furnish the most cases, this being the time of life when cares and worries are most abundant, when uterine disease is most prevalent, and when the nervous system is probably most open to influences of every kind.

Pathology.—Of the morbid anatomy we know nothing, as the disease is never fatal.[2]

Pathogenesis.—When we try to frame for ourselves an explanation of the connection between the different symptoms of this complex of symptoms which we call mucous colitis or mucous colic, it seems to me that we must look upon the bowel trouble as but one of the many disturbances of nerve function, whose totality we sum up in the convenient term neurasthenia.

As there is scarcely any organ of the body which may not at some time become the seat of disturbed nerve function, and as every abnormal functional activity is accompanied by abnormal metabolism, we may, I think, look upon this secretion of mucus—abnormal both in kind and in degree—as the metabolic product of glands whose particular nervous apparatus has become involved in the general nervous derangement which obtains in these cases. Nor are analogous secretory disturbances of other organs wanting to strengthen this view. Witness in hysteria the "spastic" urine, the continued secretion and vomiting of watery fluid from the stomach, the prolonged salivation—all these point to abnormal metabolic glandular activity, the result of disturbed innervation. The bowel trouble, once established, in itself tends to become a cause of further nervousness, partly through that depression of spirits which every abdominal pain brings with it, partly by increasing the hypochondriacal tendency through directing continuous attention to an organ or a function, in a way so marked that the patient is unable to distract her mind from it, even if she would. Thus, that which in the beginning was an effect now becomes a cause, and we have established a vicious circle which tends to perpetuate itself indefinitely.

And it is, I think, only by keeping this essentially

[1] Trans. London Pathological Society, vol. ix., 1858.

[2] Hence the name "mucous colic," which Nothnagel ("Darmkrankheiten," Berlin, 1884) proposes for this affection, and which really seems preferable to any heretofore in use.

[1] Edwards (Keating's "Cyclopædia of Diseases of Children," Philadelphia, 1890) says: "In one hundred and eleven cases six were under the age of ten."

[2] The case reported by Edwards (Amer. Jour. Med. Sci., April, 1888) cannot be looked upon as one in point, for although mucus in cord-like masses and in flakes and patches was found post mortem, yet the patient gave no clinical history of having had mucous colitis during life.

neurosal view of the nature of the trouble in mind that we can proceed to a rational treatment.

Treatment.—If we take the view that mucous colitis is a form of neurasthenia, a rational treatment will naturally resolve itself into treating the basic cause; and this course has, in fact, yielded to me the best results.

My plan, speaking generally, is to combine the "rest cure" with irrigation of the bowel. If possible, I put the patient to bed and keep her there, feed her systematically with milk, have her massaged, and have the large intestine thoroughly washed out once a day. Milder cases need not be put to bed, but the improvement of their nutrition through plenty of food or the copious use of milk in some form must be insisted on. I often tell these patients that if they can manage to gain ten pounds they will probably be cured. It is, of course, the increased nutrition of the nerve cells which causes the morbid symptoms to disappear. Milk is chosen because, as these patients have usually a very poor appetite, they can most easily be nourished in this way. But as the appetite improves, a liberal and varied diet should be urged. It is a mistake to keep these patients on milk with the idea that this in itself will cure the intestinal dyspepsia of which they are considered to be the victims. If persisted in with that idea, the patient usually grows worse instead of better.

The method of intestinal irrigation to be pursued is not indifferent. No good can be anticipated from enemas taken by the patient while standing up or sitting on the closet. It must be our aim thoroughly to wash away all the mucus from the colon. To do this, two quarts of water or more should be used in a fountain syringe. The patient must lie upon the left side, the knees drawn up to relax the abdominal muscles, the hips on the edge and the shoulders toward the middle of the bed, so as to raise the hips higher than the rest of the body—a modified Sims position. The water, in which a dessertspoonful of borax may be dissolved, and which should be at about the temperature of 100° F., is then allowed to flow slowly into the rectum, whence gravity will carry it into the colon. It is rarely necessary to use a long rectal tube, especially as many patients object to it. By allowing the water to flow very gradually and by having it at about the temperature of the body, all straining is avoided, and patients quickly learn to hold a quart or two of water and to retain it for from ten to twenty minutes. When this is then passed, large quantities of mucus generally come away with it. The best time to give the enema is about ten o'clock in the morning. By that time the bowels will usually have moved, and the action of the water upon the empty intestine will be all the more complete. When there is constipation, I order either a mild laxative at bedtime or a glass of hot water with some Rochelle salts to be taken on rising.

As there is no class of patients in whom the influence of the mind over the body is greater than in neurasthenics, it is of the highest importance to keep these patients well in hand, impressing them with the necessity of strict and minute obedience to orders, and at the same time encouraging them in the belief that they will get well. In many cases the co-operation of an intelligent nurse is absolutely essential, especially if the patient be put to bed. In every case the patient must consent to make the systematic care of her case the first consideration, with which no social or other obligations can be allowed to conflict. And unless this be done, little can be hoped for.

The surroundings of the patient must be carefully inquired into, and household, family, or business cares, as far as possible, removed. The good effects which so often are seen to follow a trip to some milder climate are doubtless as much due to the improved mental atmosphere—the absence of household cares or of business worries—in which the patient now moves, as to the salubrity of the place itself. Such a journey is, therefore, by all means to be recommended when practicable.

Of drugs I have so far said nothing, and, indeed, they play but a minor part in the treatment. If there be anæmia—and there generally is—iron and arsenic and strychnine should be given. And let me say, in parenthesis, that after trying most of the new preparations of iron so highly vaunted, I believe nothing is better than the old ferrous-carbonate pills known as Blaud's pills, provided they are well made and fresh—and they frequently are neither. The newer peptonized preparations I find useful to fall back upon when the time comes when the patient tells you that "she thinks the iron is beginning to disagree with her," for there is nothing like having many strings to your bow, even though they be all alike.

When there is much fermentation, intestinal antiseptics are of limited use. Creosote, bismuth salicylate, and bismuth subgallate I have used with apparent benefit; but let your motto be, the fewer drugs the better.

Duration.—With regard to the duration of treatment, no fixed time can be set, but six weeks should be stated to the patient as the minimum, and it may seem best to extend it over several months.

Prognosis.—The form of treatment just outlined has yielded in some cases most brilliant results; in others the failures have been no less conspicuous: while in yet others there has been considerable improvement, lasting for varying periods after the treatment had ceased. And this, taking the neurotic origin of the affection into consideration, is what might have been predicted.

I believe that the prognosis will always be found to hinge upon the particular grade of neurasthenia with which we have to deal, and only treatment will reveal what the particular grade is. The prognosis will be bad in those cases in which there seems to be an ingrained vice of the nerve cells—a deficiency in their anatomy—which no art can overcome; and it will be good in proportion as the nerve cells are amenable to functional restoration.

In practice it will be found impossible to say to what class of neurasthenics—the curable or the incurable—patients belong, till you put them to the test of treatment. Some of the severest cases recover; some of the mildest persist, in spite of every effort to cure them. Others, while apparently recovering, suddenly, without any apparent cause, relapse into their original condition. In these latter cases it would seem as though the nerve cell, after having been laboriously built up, was too feeble to bear even its own weight, and collapsed.

I believe that often a tolerably shrewd forecast can be made by observing the type of woman to be dealt with—in general, the prognosis in the neurotic type being better than in the hysterical. The neurotic woman is intelligent, sensitive, zealous, unselfish, wearing herself out for others; while the hysterical is purposeless, selfish, introspective, and capricious. This type of woman seems to lack the necessary fixity of will essential to getting well.

I cannot, I think, give you a better picture of the disease than by presenting the brief histories of a few cases.

Case I.—Mrs. R. R. H——, aged thirty-seven, married ten years, and mother of four children, whose various serious illnesses have caused her continued anxiety. About two years before her marriage she had had a severe attack of diarrhœa, lasting two weeks. After her marriage she began to have diarrhœal at-

tacks, lasting a few days at a time, and coming on every two to three months. These attacks gradually increased in frequency and duration, and were generally sure to follow any unusual exertion. Owing to the severe and prolonged illness of one of the children, she became very nervous and much run down in body and spirits, though naturally a woman of superior intellect and strength of mind. About a year before she came under my care, she had taken a trip to Boston for recreation, hoping the change would do her good. But it proved anything but a recreation, for immediately on her arrival she was seized with one of her diarrhœal attacks, so severe as to keep her six weeks in bed. While formerly the attacks had consisted of simple watery discharges without pain, on this occasion she first began to notice pain in the abdomen. Ever since this last prolonged seizure, she had had at intervals attacks of abdominal pain, coming on pretty regularly about 4 A.M., followed by movements, of which the first would be solid, the following two or three watery. Later in the day the movements, if any, would be normal. She had never looked at the movements particularly, so could not tell their character. There was much flatulency, both gastric and intestinal.

Examination showed the patient looking thin and pale. Weight, one hundred and five pounds. Abdomen unusually sunken and the walls devoid of fat. On palpation, areas of pain were discovered along the course of the transverse and descending colon. Nothing abnormal was discovered about any of the other organs. No uterine disease. The stools examined contained numerous small masses of mucus. Special search was made for the amœba coli, but none was found.

Treatment consisted of absolute rest in bed, the patient not being allowed to get up even to go to the closet, but being obliged to use a bed pan. Fluid diet—three quarts of milk daily, in divided portions every two hours; general massage once a day, and intestinal irrigation every morning about ten o'clock. Creosote was given in maltine for the flatulency, and iron for the anæmia. The milk diet was varied later by the addition of scraped meat and farinaceous foods.

Under this treatment the patient steadily improved. The early morning pain and diarrhœa disappeared first; later the abdominal tenderness grew less and less, and finally disappeared; and a marked improvement took place in her whole appearance and manner. She was kept steadily in bed on the above treatment (in which I was ably assisted by a faithful nurse) for eleven weeks, and when she finally was allowed to get up, it was found when she could be weighed that she had gained twenty pounds. Although, almost on the very day of her being allowed to go about generally, one of the children was taken seriously ill and had finally to be operated upon, which necessitated the mother's constant care for many weeks and was a great strain upon her in every way, no relapse occurred. This lady was treated in the summer of 1892. In the four years that have elapsed she has, on the whole, enjoyed excellent health. She has stood the test of another confinement and of various illnesses among her children, without breaking down. She has had occasional attacks of her old trouble since, but has never become so run down as before. After nursing her husband through typhoid fever last summer, she had a rather prolonged attack in the fall, but recovered from it without having to go to bed. I saw her a few weeks ago, and she looks and feels well, weighing now about one hundred and fifty pounds, against one hundred and five pounds when first put to bed for treatment.

This case presents that type of neurasthenia in which the nerve cells are capable, by forced nutrition, of being built up, and, once built up, they maintain their integrity. This case illustrates well what I have before insisted on, namely, that so much depends upon the mental calibre of the patient. This lady, as already stated, was a woman of unusual good sense and intelligence. She made up her mind that although it was necessary to make considerable sacrifice in order to get well, it would be worth the trial. And having come to that conclusion, she adhered rigidly to her determination. Since her recovery she has kept up her general health much better than before. She still drinks a goodly quantity of milk every day, and this undoubtedly has had much to do in preventing a relapse.

Case II. presents a different type of patient and consequently of the disease. Mrs. G. C. S——, aged about twenty-six, married and the mother of two rickety children, was referred to me by Dr. Gibney, who was treating one of the children for fragilitas ossium. Since the birth of the youngest child, twenty months previously, the patient had been suffering from the effects of a lacerated cervix and perineum. These had been operated upon about a month before she came under my care, and she was feeling better in consequence. She gave a history of having led a life of fashionable dissipation before marriage, and of having had an attack of "nervous prostration" just prior to her wedding. Since the birth of her first child she had never been well. About two years before I first saw her, she first began to notice abdominal pain and the passage of strings of mucus, which she thought were the "lining membrane of the bowel." Her general habit was a very constipated one, the bowels never moving without laxatives.

The patient was a delicate-looking brunette; weight, one hundred and three pounds, having been one hundred and twenty-five pounds before marriage. Examination showed a very moderate degree of abdominal tenderness, and nothing else. She was put upon the routine treatment of feeding with milk, giving massage, and intestinal irrigation, which she adhered to with some regularity in the beginning, but soon allowed social duties to interrupt. At Christmas time she stopped all treatment for a while. However, she gained five pounds in weight and felt a good deal better, and had learned that she could drink milk without becoming "bilious," which she had heretofore thought impossible, when an attack of the grippe prostrated her utterly, so that it was nearly two months before she could leave to go to Lakewood. In the fall she fell into the hands of one of the beef and hot-water specialists, under whose treatment she remained for about six months, without any improvement. She now lives in the country, is not much better than formerly, but finds, I am told, that intestinal irrigation gives her more relief than anything else.

This was a case in which the mental fibre was as weak and flabby as the physical. The intellectual development was not marked and the will power feeble, and I believe that this patient is, in consequence, condemned to a chronic invalidism.

Case III.—William P——, aged forty, a man of large affairs and a very successful business man: formerly had many financial cares, but now has none at all. He is rich, but works as hard as ever, and has scarcely any mental resources outside of business, but, fortunately, is fond of riding and driving. He says that he fears "nervous prostration," does not sleep well, and is nervous and apprehensive, and unable to apply himself to business as well as usual. Of late he has noticed pain in the abdomen, coming on in the early morning and necessitating going to the closet. The bowels are irregular; often loose, with frequent strings of mucus mingled with the fæces. The urine shows traces of albumin and a few hyaline casts.

There is much oxalate of lime deposit. No high-tension pulse is to be felt, and the heart is not enlarged.

He was ordered irrigation of the colon, a meat diet, and iron, and to take more recreation. The patient improved considerably under this, and later went to Florida for a month. On his return he slept well and all the old nervousness and apprehension had passed away. The bowel trouble disappeared, as well as the trace of albumin and the casts from the urine. At my advice he changed radically his mode of life, gave up many of his business interests, cut down his work, cultivated the pleasures and amenities of life, and devoted some of his business abilities to the management of philanthropic enterprises. This was three years ago, and he has had no sign of nervous prostration or of mucous colitis since, and is in every way a healthier and a happier man, and I may add that he has become almost as devoted to golf as he formerly was to business.

Case IV.—Mrs. L——, aged forty-two, widow, with one grown daughter, says that for the past twenty years she has had flatulent dyspepsia and obstinate constipation, for which treatment has given but temporary relief. About six months before consulting me for the present trouble, she began to notice pain about the region of the navel, coming on every morning about four o'clock. On going to the closet she would have a normal movement, after which the pain disappeared. She had not inspected the movements, so could not say whether mucus was present or not. She was nervous and run down.

Examination: Patient was pale and thin, weighing one hundred and eight and one-half pounds. The abdomen protruded markedly between the recti muscles on coughing. There was very slight pain on pressure over the lower part of the descending colon and the sigmoid flexure. The day after examining the patient I was hurriedly called to see her early in the morning, as she had had most excruciating pain, caused by the passage of a round mass of yellowish-white, tough mucus, the size of a small orange. The pain ceased when this mass, which was slightly streaked with blood, came away.

Treatment: The patient was put to bed and kept there strictly, with a nurse to look after her. The diet was milk only, three quarts a day. High enemata of one quart of water with two drachms of boric acid were given every morning. Bismuth salicylate, twenty grains by the mouth, was given three times a day.

In two weeks' time the movements following the enema, which had originally been full of mucus, were almost wholly free from it, and there was a marked improvement in the general health and tone of the patient. Just about this time she had a most severe attack of the grippe, with broncho-pneumonia, which at one time threatened to be fatal. For nearly a month she had temperatures ranging from 101° to 103.5° F. This naturally necessitated stopping the bowel treatment. However, on recovering from her broncho-pneumonia, she had no return of the bowel trouble and was in better health than she had been for a long time, and looked upon herself as fully cured. I saw nothing more of her, but I infer that she had a relapse and that the abdominal pains returned, for I learned through friends that about a year later she had had both ovaries removed by a gentleman who is known to remove ovaries on the very slightest provocation. As the lady had been a patient of mine for several years before treating her for this particular attack, and as there had never been the slightest reason for believing that anything was wrong with her ovaries, I cannot help surmising that her ovaries were offered as a sacrifice to her mucous colitis by this too facile operator.

I do not wish to weary you with the recital of too many cases, but I would like to add one more, which is instructive in several ways. It shows how long a patient may have this trouble, and also what positive harm may be done by not having a clear conception of its real nature.

Case V.—Mrs. C——, aged thirty-seven, married at nineteen, and the mother of two healthy children. Her present trouble began when she was seventeen (twenty years ago!), with recurring attacks of diarrhœa. The movements were watery or pasty, and contained a little mucus, never any blood. She would have some pain and uneasiness about 6 A.M., followed by a movement, which gave relief. She sometimes had as many as twenty movements in a day. These attacks had continued off and on ever since, being generally brought on by some fatigue or mental emotion. No treatment had been of any avail. She had been treated for "catarrh of the bowels." Since July 10, 1895, up to the time that I saw her first—July 19, 1896—she had been on an absolute milk diet, not having eaten during that time—as she expressed it—"as much as would amount to a loaf of bread or a pound of meat." Part of this time she had been on peptonized milk, and she had taken drugs without number, all to no effect. At the time I saw her she was having from three to five movements a day, sometimes as many as twenty. Her weight then was ninety-eight pounds. Fifteen months before she had weighed one hundred and twenty-six pounds—a loss of twenty-eight pounds under a milk diet and drug treatment.

Examination: The patient was a small brunette, with snappy eyes, and of the nervous, energetic, sensible type of woman—not hysterical. The abdomen, I found, had marks of having been repeatedly blistered over the course of the large intestine. There was slight tenderness on deep pressure over the descending colon. The movement that I saw was pasty, but looked like well-digested material, and contained no mucus. Her tongue was coated.

For treatment, I told her to stop all drugs absolutely, and to take daily at 10 A.M. a high enema of borax water. I ordered her a liberal diet of meat and green vegetables and fruits, restricting only the carbohydrates on account of flatulency. I also urged her to go out, and not to consider herself in any way a sick woman.

Ten days after this treatment was begun her abdominal morning pains had disappeared, her movements had been reduced to one formed one a day, her tongue was clear instead of being coated, and she said that she felt perfectly well again. I ordered her, consequently, to stop the enemas and to regard herself as no longer a patient.

In a month after beginning treatment (or, to speak more correctly, after discarding treatment) she had gained seven pounds, and looked and felt like quite another woman; for whereas she had formerly feared to leave the house on account of bringing on inconvenient seizures of diarrhœa, she now entered eagerly into all her husband's yachting excursions. Occasionally she would have a few loose movements, but these did not persist nor cause any distress.

This case illustrates how little is to be gained—indeed, how much harm can be done—by regarding these cases as intestinal dyspepsias, pure and simple, and treating them as such.

I have notes of many other cases, but I think it needless to reproduce them here. The typical symptoms are present in all, varying only in degree; but I hope that the cases I have cited will suffice to arouse interest in a condition which is, I think, often overlooked, and—in my experience, at least—is frequently misunderstood.

Fennel Oil in dose of five to ten drops twice daily is reported to be efficacious in whooping-cough.

THE RADICAL CURE OF UMBILICAL HERNIA BY OMPHALECTOMY.

By JOSEPH RANSOHOFF, M.D., F.R.C.S.,

CINCINNATI.

The division of umbilical hernias into the congenital and acquired has long been fixed, since they differ in etiology and, to a certain extent, in their anatomical relations. In the present paper I beg to limit consideration to the umbilical hernia of adults.

In all its phases this has been, from the infancy of the art chirurgical, the most dreaded and the least cared for of the more common varieties of rupture. The rapidity with which gangrene develops in comparison with other forms of strangulated hernia and the relatively large fatality of relief operations must account for this former dread. For the long neglect in the matter of radical treatment, other than retention by truss, to which the non-strangulated hernias of the navel have been subjected three factors are responsible. First, the mechanical difficulties of the operation inherent in the abdominal parietes; second, the complications, visceral and omental, within the hernia; and third, the very general tendency to recurrence. A brief consideration of these factors seems warranted, since it entails the better comprehension of the sources of failure and points the way to methods that make this less frequent.

The mechanical difficulties afforded by the abdominal walls are ordinarily a very thick layer of adipose tissue, in the depths of which, often two or three inches removed from the wound margin, there is found a small hernial ring. In three of the cases to be appended, this layer of fat, with the old operation of median incision, would have made the closure of the ring in the depths of the wound very difficult. Added to this layer of fat, in hernias that are larger than the size of a walnut, there is a very thin layer of integument, a spread-out covering of the umbilical cicatrix, which after operations even aseptically made is prone to undergo necrosis and be the cause of a late wound infection. The chief obstacle to success, so far as the abdominal wall is concerned, is in the hernial ring itself. As a rule, it is an aperture the margins of which are thin, rigid, and difficult of approximation, even when the ring is an inch or less in diameter. In yet other cases, from omental adhesions or the use of convex pads, the margins are very much thickened and rigid, but none the less difficult of approximation. It is for this reason probably that most operators have at one time or another seen the necessity of enlarging the fascial aperture or excising it altogether, to be enabled to bring about a fair apposition. The most perfect approximation of the umbilical ring, when firmly united, still leaves no muscular covering between the peritoneum and the integument. The tendency to recurrence with every renewed tension upon the abdominal wall, such as would occur during pregnancy, would necessarily follow.

The visceral and omental complications of umbilical hernia form the source of greatest anxiety during the operation. In hernias of small size, though irreducible, the contents are, as a rule, limited to a large mass of omentum, which, though adherent in one or many places to the sac or the ring, can ordinarily be separated with little difficulty and removed. In the larger hernias there is almost invariably found a part of the transverse colon, and not infrequently many coils of the small intestine. While the latter do not ordinarily form adhesions, the transverse colon is prone to become adherent to the sac wall or to the omentum, or to both. To complicate further the relations, the sac is, as a rule, multilocular and divided into imperfect compartments by the presence of bands stretching from wall to wall. Fortunately, in these cases the hernial ring is, as a rule, very large, for which reason strangulation at the ring is a comparatively infrequent occurrence in these cases of umbilical hernias that resemble eventration. Nevertheless, even here obstruction of the protruded intestine is followed by colicky pains, vomiting, or gastric disturbances often enough to make it necessary to attempt a radical cure; or, if this is not feasible, so to enlarge the ring by incision as to preclude the probability of temporary obstruction. In these large eventrations much has in recent years been accomplished by radical operation; the only limit to operative interference would be so contracted a condition of the abdominal cavity as to prevent or preclude the probability of a return of the protruded intestine without the danger of inducing obstruction. There is no phase of abdominal surgery in which the danger of unintentionally wounding an adherent intestine is greater than in these large umbilical hernias when operated upon by the old method of the single median incision.

From the foregoing, the tendency to recurrence in cases operated upon by the older method is in part explained. The imperfect apposition of the margins of the ring, the absence of a muscular covering, unequal pressure on the wound margins by the interrupted suture passing through the entire thickness of the abdominal walls, the tendency to fat necrosis and sloughing of the integument, are all held accountable for the immediate failures often obtained and the very decided tendency to recurrence. Within recent years three very decisive steps have been taken to overcome the obstacles to success theretofore existent.

The first of these is the excision of the umbilical ring in all radical operations; the second, the suturing of the median borders of the recti muscles to each other; the third, the closure of aponeurosis and muscle by a suture separate and distinct from that of the overlying adipose and cutaneous layers.

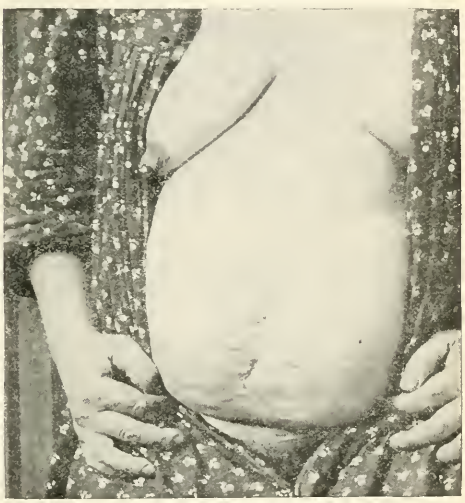
In 1888 Keen was forced to resort to excision of the ring in a case of strangulated hernia. Before that, in 1866, Storer had already resorted to this procedure, which probably has been forced on many operators. It remained, however, for Condemin, 1892, to elevate his procedure into a distinct method of operating for umbilical hernia. His object from the beginning is to excise the hernial ring, for which purpose he opens the peritoneum by elliptical incisions which meet above and below the median line and are carried directly down to the peritoneum outside of the peritoneal covering. After division of the skin, adipose layers, and fasciæ, he opens the peritoneum on the outer side of the ring itself. The single median incision is therefore discarded entirely. In the cases in which I resorted to this procedure, and two of them were of very large hernias, the operation proved to be very simple. It very greatly facilitated the return of the reducible portion of the hernial contents, and after the splitting of the sac, subsequently made, lessened, it seemed very greatly, the difficulties of separating adherent omentum and intestine. In one of the cases the hernia was quite as large as an adult head, the patient being of short stature and weighing over two hundred pounds. Except for the elliptical incision, the task of exposing thoroughly the ring and of severing adhesions of omentum and transverse colon would have been extremely tedious and accordingly dangerous. A further advantage of the complete excision of the hernial sac, with all the coverings of the hernia, together with the ring, is that at the close of the operation the conditions of the wound are best suited to primary union. The attenuated skin, the surrounding fat, the fibrous margins of the hernial ring, which are liable to necrosis, are removed, so that the wound really is like that left after the ordinary median lapa-

rotomy. In this method of operating, furthermore, there is included, as a rule, by necessity, the suggestion made by Gersuny in 1893, to suture together the median borders of the recti after opening their sheaths, in order that a continuous muscular plane may oppose the recurrence of the hernia. Unfortunately, the subjects of acquired umbilical hernia are usually women blessed with more fat than muscle, and the recti are found to be poorly developed, atrophic, or the site of fatty infiltration, so that in them too much importance must not be attached to the completion of the muscular plane between the abdominal cavity and integument as a preventive of recurrence. A third step in advance has been made in the separate suturing of the fascia and muscular layers on the one hand, and the integument on the other. In the four cases recorded, I have resorted to the silver-wire buried suture for the deeper structures, and the subcutaneous suture for the superficial part of the wound. In only one of the cases, that of the largest hernia, did secondary infection follow on fat necrosis. The deeper portion of the wound was not opened by the mishap. It is nearly a year since the operation was performed and a recurrence has not taken place. In a second case, in which the radical operation followed the relief for strangulation, a similar wound complication resulted. In one of the cases, which healed *per primam*, an abscess formed about the ligated omentum four months after the operation and discharged through the abdominal wall. In three of the cases which I beg now to report the operation was that of radical cure by omphalectomy. In the fourth case, that of a strangulated hernia, the omphalectomy was made secondary to the old operation.

Case I.—Mrs. S——, Dayton, O., aged forty-nine years, widow, has given birth to ten children, the oldest twenty-seven years of age. She has had a hernia since the birth of her last child, ten years ago. It was at first reducible, but, notwithstanding the use of trusses, has grown very much and become irreducible. She has never had any strangulation but has suffered very much from colicky pains and constipation, which attacks come on at irregular intervals of one or two months, and confine her to bed for days at a time. When not so affected she is able to do her work as a laundress. During the last two months she has been almost entirely unable to work.

Present condition: Very fleshy woman, little over five feet in height, weighing between two hundred and two hundred and ten pounds. Presents an umbilical hernia nearly as large as an adult head, within which portions of the colon can be readily mapped out by percussion. On a rough estimate, about one-third of the hernial protrusion is reducible. What feels like an omental mass can be outlined within the tumor. The hernial ring has a measurement of about six inches in its long diameter and three in its transverse. Owing to omental adhesions the outline of the ring cannot be everywhere distinctly felt.

Operation, October 25, 1895, at the Good Samaritan Hospital, morphine and A.-C.-E. anæsthesia. An incision beginning about three inches above the upper margin of the hernia in the middle line, surrounding it on both sides, and terminating a like distance below in the median line, was made. After dividing the abdominal wall, layer after layer, upon either side, the subperitoneal fat was reached and the peritoneum opened on the left side, the finger being used as a guide. Incision was made through the peritoneum upward and downward, completely encircling the ring upon its left side. By retracting the median margin of the wound, the ring was readily exposed to view, and the entrance through it into the hernia of the omentum, parts of the transverse colon, and of the coils of the small intestine could be seen. With the intestine exposed, reducible portions of the hernia were returned to the abdominal cavity, where they were retained with large gauze aprons. To facilitate the return of the adherent portions, the ring and the hernial sac were now divided from within and the adherent contents completely exposed. There were many large and small apartments in the hernial sac. The entire omentum was contained within the sac, adherent in many places, but for the most part converted into an irreducible fibro-lipomatous mass, which was removed, after ligation, in four divisions. The adhesions of the transverse colon were likewise separated without much difficulty. The removal of the hernial sac, together with the overlying integument, was completed by division of the peritoneum in the line of the ellipse upon the right side. Closure of the wound was made by buried silver-wire mattress sutures. The external wound was closed by buried silkworm-gut sutures. To prevent pocketing, three deep silkworm-gut sutures were placed through the entire thickness of skin and fat layer of the abdominal wall. When completed,



the wound resembled an ordinary laparotomy wound about ten inches in length. Time of operation, forty-five minutes.

Subsequent history: The patient made an uninterrupted recovery, except that a fat necrosis developed within the grasp of one of the interrupted silkworm-gut sutures. This was followed by suppuration on the fourteenth day and somewhat protracted recovery. There never was any elevation of temperature above the normal. The patient was discharged well December 8th, six weeks after operation, without abdominal support.

Case II.—Mrs. J. D——, aged sixty years, of Richwood, Ky.; married, mother of six children. She has had an umbilical hernia for many years, and has frequently suffered from colicky pain. She was seized with violent pain, vomiting, and obstipation on April 9th, when she was seen by Dr. Duncan, of Walton, Ky., who recognized the presence of strangulation. When seen thirty-six hours after the inception of the symptoms, the patient presented an umbilical hernia the size of a large walnut, tender to the touch, and irreducible. The integument covering it was very thin, and through it a mass of omentum could easily be distinguished. The usual symptoms of acute strangulation were present.

Operation, under A.-C.-E. anæsthesia. Incision in the middle opening of the sac revealed a well-marked

strangulation by a ring one-half inch in diameter. The contents were an adherent mass of omentum, beneath which was found a coil of the small intestine tightly held by the ring. When this was divided, the intestine was readily brought into the wound, and, being found healthy, was returned. The omentum, adherent to the sac wall in a number of places, was removed after ligation of the pedicle. When the sac had been removed it was found that the edges of the ring were very much attenuated, rigid, and difficult of approximation. An incision was therefore made one-half an inch above and below the margins of the ring, and this completely dissected out. The sheaths of the recti muscles were by this procedure opened and readily approximated. The superfluous integument was removed by two semilunar incisions and the wound closed by deep and superficial sets of sutures. This patient made an uninterrupted recovery, save for a limited sloughing of the fat contained between the superficial and deep sutures. The hernia has not returned.

Case III.—Mrs. S. R——, of Greeley, Col., operated upon at the Jewish Hospital, January 4, 1895. Patient, aged fifty-nine years, mother of four children, has had an umbilical hernia for many years. She has never had attacks of strangulation, but frequent attacks of colicky pain, gastric disturbance dyspeptic in character, and cardiac palpitation. These are almost always developed after the ingestion of a full meal, and are associated with severe pain in the hernia. At other times the hernia presents nothing indicative of its relation to the gastric symptoms presented.

Present condition: Patient has a small umbilical hernia the size of a walnut. The abdominal wall is densely covered with fat and is pendulous; the hernia is covered with attenuated skin, through which adherent omentum can be outlined.

Operation: A.-C.-E. narcosis. An elliptical incision completely surrounding the hernial tumor and beginning an inch above and terminating an inch below the median line was made. The incision was continued through the entire thickness of the abdominal wall, including the peritoneum. The peritoneum was first divided on the left side, when the omentum could readily be discerned entering through the hernial ring. Since no intestine entered at all, the incision was made through the peritoneum upon the opposite side, and the hernia, together with the omentum, drawn into the wound. The latter was ligated at its point of entrance into the sac and returned to the abdominal cavity. The operation was completed by deep, buried silver-wire sutures and subcutaneous silkworm-gut sutures. The patient made an uninterrupted recovery. She was discharged from the hospital, February 10, 1895. Three months later she developed an abscess about the omental stump, which was opened through the abdominal wall in the region of the gall bladder. With the outflow of pus there was discharged the ligature placed about the omentum. This is the only case in my experience in which the ligation of the omentum has been followed by suppuration.

Case IV.—Mrs. J. C——, Cincinnati Hospital, married. Admitted to the service, April 24, 1896. She has in the last years been very fleshy, and for ten years has had an umbilical hernia, which has, through frequent attacks of colic, interfered with her work as housemaid. The hernia is about the size of a large fist and irreducible. Pressure upon it is painful in places. Intestinal contents cannot be discovered.

Operation, April 25, 1896, as in previous case. The sac contained almost all of the apron of the omentum, which could not be returned and was removed in sections after ligation with strong catgut. The hernial ring measured an inch in length by three-fourths of an inch in width. The umbilical ring, and all of the overlying soft parts included within the elliptical incision, were then removed and the wound was closed with deep silver and superficial silkworm-gut sutures. The patient made an uninterrupted recovery.

The cases reported have been operated on within two years, a period too short to warrant conclusions as to the permanence of the cures. Nevertheless, it must be borne in mind that in umbilical as in post-operative ventral hernias the visceral protrusion usually occurs within a few months of the operation. In all of the cases the abdominal wall at the wound site is firm, and I hardly look for recurrence. The salient features of the operation as performed, namely, excision of the ring, suture of the recti muscles, and buried metallic sutures, form the basis of my confidence in the results obtained. Should further experience fail to shake it, it is certain that many patients with umbilical hernias can by this method be rescued from what is always a source of great annoyance, and often a direct menace to life.

TREATMENT OF TYPHOID FEVER.

By J. L. C. WHITCOMB, M.D.,

LIBERTY, N. Y.

It has been my good fortune never to have lost a case of typhoid fever. During the past six years, which covers the whole of my professional career, my notebook shows that I have treated ninety-seven cases, some of them falling into my hands during the third or fourth week of the disease, some of them neglected cases, which I entertained little hope that any form of treatment would bring to a successful issue, some of them complicated by pre-existing heart, kidney, or lung disease of a more or less serious nature. Therefore I use the words "good fortune" advisedly, as I am well aware that the element of fortune must enter largely into such a series of consecutive unselected cases unbroken by a single death, no matter what the treatment. Especially during the earlier years of my practice the uniform success which attended my treatment of this disease was regarded by me as largely fortuitous and not the result of the treatment. However, as my cases multiplied in number, the conviction grew on me that there must be some intrinsic merit in any treatment that resulted in one hundred per cent. of recoveries in a disease with a normal mortality rate of from twenty to forty per cent. During the months of September and October of the past year I treated eighteen cases of typhoid without a death. These, with my former cases, making nearly one hundred in all, and all being treated after the same plan, have led me to report my method of treatment to the profession, believing it is worthy of more extended trial.

With the possible exception of malaria, typhoid is more common and more widely diffused than any other disease. There is no climate or soil where it is unknown, no race or condition of men which is exempt. Man cannot flee from it, as he undoubtedly carries its germs within the recesses of his own bowels. The innocent bacillus coli communis requires but the proper conditions of soil, heat, and moisture, after it has passed from the bowels, to become the deadly germ of typhoid, ready to contaminate springs and wells and all drinking-waters not properly protected. Although so widely diffused, its germs so omnipresent, it would seem that it can be more easily controlled by proper sanitation and hygiene than any other of the infectious diseases; and when once contracted it is more amenable to correct treatment, as has been demonstrated by Brand and others. In spite of these well-known facts, eminent physicians have reported series of cases

during the past year, showing mortality rates ranging from fifteen to twenty-five per cent. The recent deaths from this disease of a number of persons of nation-wide reputations have served to emphasize the fact that it is still unconquered, even when all the advantages which wealth and science can command are arrayed against it.

The grand, almost perfect results obtained by the Brand treatment seem unable to induce any great number of the profession to adopt its cumbrous and costly technique in private practice. This is partly explained by the fact that many patients will not submit to what appears to them a very formidable procedure, while others will insist that a less heroic treatment be tried at first and will yield to the advice of their physicians only when it is perhaps too late. Flesh and blood shrink instinctively from the severe requirements of the tubbing process. It will never become popular, or the routine practice of the profession, any more than hypodermatic medication will ever become popular, no matter how much its advocates may laud its superior merits.

In this country we still, unfortunately perhaps, have to consult the tastes and predilections, often the whims and fancies of our patients in the matter of treatment of their ailments. I fancy this is one of the reasons why the charity patient in the hospital gets well of his typhoid while the rich man dies, a victim to his own high privilege of bossing the doctor. They do these things better abroad, especially in Germany. While we can take our treatment from Germany, we cannot take our patients from that country, where the martyr-like submission of the patient to his doctor is only equalled by the docility of the guinea-pig in the hands of the bacteriologist. In this land of boasted freedom, it is doubtful if Brand would ever have demonstrated to an admiring world the possibility of curing all cases of typhoid. His investigations would have long since come to an end from lack of material with which to experiment. I was an early convert to the Brand treatment, but the impossibility of carrying it out among the class of patients which form so largely the clientèle of the medical fledgling prevented me from ever giving it a trial.

Necessity was ever the mother of invention, and it was sheer necessity that led me to adopt the method of treatment that has stood by me so faithfully—the necessity of giving my patients the benefit of the principle involved in the Brand treatment, so far at least as was possible without the impracticable apparatus of that treatment. I have always claimed that my treatment was but a modification of Brand's. In my opinion Brand did more than discover a successful treatment for typhoid. He discovered a principle of treatment, which principle may be as successfully applied in a more convenient and agreeable manner than by the impracticable tubbing. This principle may be formulated thus: The chief indication in the treatment of typhoid is the sustaining of the nerve centres rendered inert by the typhoid toxæmia, and this indication is best met by the application of cold to the body. Brand and his followers maintain that the cold baths are not to reduce the temperature so much as to stimulate the nerve centres to maintain the vital functions until the fever has run its course. I believe this principle of treatment is fully met by systematic cold sponging if properly applied. I am aware that this is denied by the advocates of the tub, who also deny that cold envelopment, or, in fact, the application of cold in any other form has the same action as submersion. This assertion never appeared rational to me, and in the light of my experience I must take issue with them on this point. I believe the difference is one of degree and not of kind. It must be granted that submersion gives a greater stimulus, followed by more marked reaction. In this very fact there may be an element of danger. Certainly care and judgment are required to graduate the temperature of the bath to the strength of the patient, or harm may result.

It might not be fair to expect that every physician would obtain the same results as Brand obtains after thirty years of experience. It is open to question, however, if his treatment would not long since have fallen into disrepute, had not its difficulties prevented it from becoming popular. For the most part it has been tried only by men of ripe experience and under the most favorable conditions, usually in hospitals, where constant attendance of trained assistants to carry out its requirements has contributed largely to its success. It has been the fate of many a successful mode of treatment to go down in obloquy to unmerited oblivion, simply because of its too general use by unskilled experimenters.

Brand's record of twelve hundred cases with but twelve deaths, or without any deaths if we exclude those who came under treatment subsequent to the fifth day, offers little chance of improvement, unless it be in a manner to bring about the same results by a less tedious procedure. This is what I claim for the method of ice-cold sponge baths I employ, a method which, I believe, comprehends the cardinal principle of the Brand treatment, and, if conscientiously carried out, will give the same results. It will be urged that other plans of treatment have been as successful as the one herein advocated, considering the limited number of cases treated. Pepper, of Philadelphia, treated one hundred consecutive cases without a death, using nitrate of silver. It must be admitted that the number of cases is far too small to lend much significance to the plan of their treatment—that is, if they are to stand alone. If, however, the treatment followed be but a modification of the Brand treatment, as is claimed, then the import of this series of cases becomes obvious at once, and the only successful treatment of typhoid yet devised is brought within the means of every patient and its application made possible to every physician. The importance of this fact cannot be overestimated. Typhoid is a disease of the country. It usually has to be treated in farmhouses where the expensive apparatus of the bath treatment is simply out of the question. Were it largely a city disease, the difficulties might possibly be met by hospital treatment.

My method of treatment is as follows: All subjects, no matter how mild the symptoms, are put in bed at once and a sponge bath, at the temperature of blood heat, is given. In two hours another is given, its temperature being about that of the room. In this manner the patient is gradually prepared for the ice-cold sponge baths, which are now to follow every two or four hours, according as I consider the symptoms mild or severe. Ice is floating in the bath bowl after the first two baths. The time consumed in each bath is about thirty minutes. If the temperature of the patient ranges at 103° F. or above, I order the baths prolonged to forty-five minutes, the body to be gone over several times in succession, with brisk rubbing. In severe cases, when the temperature runs up to 105° F. once or twice a day, I order, in addition to the sponging every two hours, that bags of crushed ice be placed as follows: two on the abdomen, one on either thigh, and one on the head. If the patient complains much of cold, I place a hot-water bag at the feet. These are to be kept on continuously until the fever drops to 103° F., when they are removed, but the baths are continued. I also enjoin the drinking of from one to two quarts of cold water during the twenty-four hours. It is often a matter of surprise to me how little the patients complain of the cold applications. On the contrary, nearly all will express themselves as being

relieved by them, even looking forward with pleasure to the bath. The ice bags are not always tolerated with the same fortitude, their weight sometimes being complained of, yet I have never had to discontinue their use because of their discomfort. During the third and fourth week of the fever, or at any time if there be much weakness, I frequently order one-half ounce of brandy before each bath or before every other bath, according as the case demands. As a result of these sponge baths I have never noted any immediate or marked fall of temperature, but I have never yet failed to see a toning up, a brightening of the whole aspect of the patient. The tongue becomes more moist, the eye less dull, and the apathetic face assumes a livelier expression. If treatment be begun at the onset of the disease, it is rare to meet with the severer symptoms. They are usually all of a mild character. The cases of death-like stupor from profound typhoid intoxication described in the text-books are conspicuous by their absence or extreme rarity.

I am convinced that of all therapeutic measures employed to-day in typhoid, none are fraught with more good to the patient, or are capable of doing less harm, than are cold applications. Although I consider the cold applications the sheet anchor in the treatment, I have never employed them altogether to the exclusion of drugs. Consequently I cannot say whether I should have had the same results had I omitted all drugs, as is done in the Brand treatment. I am inclined much to doubt that I should, however, especially in those cases which came under treatment late in the disease, or in those which were complicated by pre-existing organic disease. If treatment be begun at the onset of the disease, or before the fifth day, I believe the results would compare favorably with the results of the Brand treatment, all conditions being similar. The chief indication being to save life and not to simplify treatment, however desirable the latter may be, I never cared to experiment in the way of seeing how little treatment would suffice to bring the patient through. The drugs I employ can do no possible injury if used with judgment, and in some cases I am convinced they do positive good. I begin the drug treatment with a dose of calomel followed by a saline cathartic. Throughout the entire course of the disease I keep the bowels open from two to four times during the twenty-four hours, using, if necessary, calomel in one-tenth-grain tablets every half-hour until the desired result is obtained. In case there be moderate diarrhœa, I do not interfere with it. If, however, there be five or more passages per day, and especially if they be watery in character or accompanied with much pain and discomfort, I give small doses of opium until the number of movements is reduced to the required amount. I invariably give strychnine sulphate, one-sixtieth to one-thirtieth of a grain every four hours from start to finish. I believe that it aids the baths in keeping the nerve centres alive to their functions.

As an intestinal disinfectant I use salol, five to ten grains every four hours. When the patient comes from a malarial district I also give quinine. The diet is peptonized milk, sometimes alternating with beef juice, beef broths, kumyss, or buttermilk.

In the treatment outlined above, there is nothing original, so far as I know. It is in fact a combination of several methods advocated by different members of the profession at the present day, namely, the Brand, the Woodbridge, and the eliminating and antiseptic treatment of Thistle, of Toronto. Between the latter two methods of treatment I doubt if there be any essential difference. In both calomel is used to keep the bowels active, and in both an intestinal antiseptic is used—in the former guaiacol, in the latter salol, the only difference being in choice of antiseptic and in some small details. In applying the treatment employed in this series of cases, it is essential to have a good faithful person, not a trained nurse necessarily, not even a pseudo-professional nurse, of whom there are so many in every community. Any person of ordinary intelligence will with a little instruction soon become expert enough to answer our purpose.

I have come to rely on the cold sponging to such an extent that I have sometimes threatened to withdraw from a case unless I could have it applied regularly by some competent person. In this series of cases there were ten of the aborted type, running from ten days to two weeks. There were four cases of hemorrhage from the bowels, all occurring after the fever had subsided, and all of a very slight character. My cases have been very free from complications. There were two cases of anterior crural neuritis, both of the right leg. Both of these patients ultimately recovered completely. There were also two cases of phlebitis of the right leg, the swelling of the limb lasting for two or three months, but finally disappearing. There were three cases of relapse, occurring on the sixth, eighth, and twelfth days respectively. I cannot close this article without expressing my unbounded admiration for Brand, whose labors entitle his name to be written alongside of Jenner's as a benefactor of his race.

THE CHARCOAL DRESSING IN MILITARY SURGERY.

By S. SHERWELL, M.D.,

BROOKLYN,

KNIGHT OF THE ORDER OF MILITARY MERIT, BAVARIA; CONSULTING PHYSICIAN, BROOKLYN HOSPITAL; CLINICAL PROFESSOR OF DERMATOLOGY, LONG ISLAND HOSPITAL MEDICAL COLLEGE; SENIOR SURGEON, SKIN AND THROAT DEPARTMENT OF THE BROOKLYN EYE AND EAR HOSPITAL; MEMBER OF THE AMERICAN DERMATOLOGICAL ASSOCIATION AND NEW YORK AND BROOKLYN DERMATOLOGICAL SOCIETIES, ETC.

THE successful use of charcoal as a surgical dressing, recently so strongly advocated by Dr. Kikusi of the Japanese army, which has been noted in many journals, and particularly in a courteous and kindly editorial reference to my own writings on the subject in the MEDICAL RECORD of November 14, 1896, impels me to reassert my own claim of original suggestion of this manner of treatment of wounds in military surgery. The subject can never lose its interest to me, and I think, if my original paper on the subject be studied, my earnest advocacy of the plan seemingly so exactly carried out by Dr. Kikusi cannot be denied.

The article of mine to which reference was made was published in the *New York Journal and Obstetrical Review* for October, 1882. It had been read the year previous in the surgical section of the International Medical Congress held in London, an abstract appearing in the published transactions of that body in 1881. It was entitled "A Ready and Convenient Antiseptic Dressing for Amputation and Other Open Wounds in Field Surgery."

In this paper I state that I had the honor of serving under Sir William McCormack and Marion Sims in the Anglo-American ambulance at Sedan, Orleans, etc., in the war of 1870–71, and had unfortunately seen a great deal of the septic and pyæmic complications following operations in our own and other field hospitals; so much, in fact, that I almost came to the belief that the methods antedating Ambrose Paré, "a clean chop and a bucket of hot tar," would have been of almost equal value, so far as saving life was concerned. Certainly very few cases of major operations escaped septic infection, more or less grave, in spite of the plentiful and various applications of the then vaunted antiseptic, carbolic acid.

After the war was over and our services had ended, I thought long, earnestly, and regretfully over this fact; and when reading of the terrible sufferings and mortality of the wounded during the Russo-Turkish campaign, at Plevna and elsewhere in later years, I wrote the article to which I refer as being read in London.

To show, then, that my method was and is identical with that of Dr. Kikusi, I must quote from the paper in question somewhat *in extenso:* "I believe a large amount of these septic complications is due to direct infection;" and after some explanatory remarks, urged the following substitute for the ordinary bandaging: "Among almost all continental nations charcoal is largely used, and everywhere available, and easily obtained; I would suggest, then, after operation, the instant envelopment of the wounds, particularly those of the limbs, and especially, as I think, those of the lower limbs, in a sack or bag (a common, small pillow-slip would serve) of charcoal, finely pulverized; a fair excess of this to be used, so as to shield and envelop the tissues; the charcoal to be either directly laid on the wound or mediately, a fold of some dressing, gauze, book muslin, or the like, being applied next the surface; this not to be removed for days at a time, except under pressing necessity, and then preferably by a jet of water from some clear source; the same form of dressing to be reapplied thereafter if fitting.

"Although this, as I am ready to admit, would not have the extremely neat surgical look of good bandaging, scientifically applied, I am convinced that in hospitals of the kind to which reference is made it would prove infinitely superior to the orthodox dressings by the infected hands and armamenta of the ignorant, dirty, or careless army nurse or aid. This charcoal dressing may and perhaps should be slightly dampened with some antiseptic or disinfectant fluid, though this, in view of the properties of charcoal itself, would seem supererogatory. I am convinced that in this way and by carrying out the *rationale* of this dressing, a certain, not to say large, amount of septic infection and consequent suffering and death in field hospitals might be avoided. The proceeding is so egregiously simple that I have hesitated many years to set it on paper, but have thought over it so long and seriously that, at the risk, it may be, of ridicule, I can hold my peace no longer."

I added farther on: "We know that the perfect carrying out of Listerism is practically impossible in the field, and I incline to the belief, which so many eminent men have recorded, that that treatment owes its success in the greatest degree to the transcendental cleanliness observed before, during, and after operation, rather than to the antiseptic (carbolic acid) and the manner of using it. At any rate, as above said, it would be hard to carry out in the impromptu services often demanded in campaigns."

The paper was closed with an urgent appeal to surgeons in any future war to give this simple and seemingly crude treatment a trial in the cases indicated and appropriate. A few remarks were added by the author as a rider, and were to this effect: That while this manner of dressing wounds might have the appearance of turning army nurses and aides into stokers, still this was in reality but a sentimental objection, as he believed that a clean, healthy wound under an apparently dirty and black exterior was infinitely preferable to the exact converse, which last is found so often to be the state of things under ordinary bandagings of the accepted and orthodox kind.

Now, as to the qualities and merits of charcoal in itself, I am not sufficiently egotistic or ignorant as to urge or believe that I was or am the discoverer of its disinfectant properties; in fact, this is distinctly disclaimed in the extract from my paper above quoted. It has been used almost from time immemorial as an adjunct to other dressings—as, for instance, in poultices or the like, in which it has played the part of a condiment, as it were. From my readings, however, I can nowhere discover that it has been recommended in the way and to the excess which I advocated in its use, until reading Dr. Matignon's articles descriptive of Dr. Kikusi's method. Hence I must claim originality for the suggestion; in fact, that gentleman (Dr. Matignon), as well as the journals—for instance, *La Médecine Moderne* (May 6, 1896)—speak of it in language that implies nothing else.

The kind of charcoal used by Dr. Kikusi was made by carbonization of rice straw (in the ordinary way of preparing charcoal). The reason for this substance being used, I take it, was largely due to the absence or scarcity of wood in certain parts of China, where wood is as scarce as on the plateaux of Dakota in our own country, and where the inhabitants keep themselves warm through the bitter winter by burning in their stoves wheat straw, twisted up into hard knots, from their almost boundless wheat fields. Dr. Matignon gives an analysis of the charcoal so prepared, in which its chemical constituents are set out at length. Without being positive on the subject, I would hesitate to believe that charcoal from that sort of woody fibre (rice straw) would be found to differ essentially from that, we will say, of any ordinary woods, there might be, I could imagine possible, a slight excess of the silicates. Be that as it may, I think, as I say, that charcoal remains charcoal, or, as the Germans put it, "*Wurst bleibt Wurst.*"

A last word may, perhaps, be permitted, as explanatory of the slight notice my paper received at the time of reading and publication. In the first place, the paper was very brief, taking scarcely ten minutes in delivery; secondly and chiefly, it was read in the surgical section of the congress just after the closing of a momentous debate, historic in character, and which no one present will ever forget—being, in short, an attack on and defence of antiseptic surgery in general, and Sir Joseph Lister's method in particular; the debate being closed by the latter gentleman in person, and having lasted all the morning session, up to within fifteen minutes of the time for adjournment. Most of the more renowned surgeons of Europe, America, and other lands were present, and many of them had spoken. The chairman gave me the option of proceeding then or of postponing the reading until the afternoon session. Since it would require but about ten minutes, I proceeded to read the paper then.

I had hoped, of course, as all authors do, to see my article reported in full in the published Transactions of the congress; but I was disappointed, I must confess, in the brevity of the abstract which appears. I seldom send out reprints of my papers published, and did not do so when my article appeared later in the *New York Medical Journal.*

As it is, however, I may conclude by expressing my satisfaction, from a humanitarian point of view, that another has arisen to carry out my idea, and, furthermore, to reap success therewith—no matter whether he has adopted it or whether it was reoriginated by him.

The opportunity of carrying out the idea has been one of the main ambitions of my life, if circumstances favoring it had arisen; fortunately, however, for the human race, such occasions are rare, and my hope is that they will become yet rarer.

A CASE OF PULSATING EMPYEMA.

By ANDREW J. McCOSH, M.D.,

NEW YORK.

Pulsating empyema is of rare occurrence. The number of reported cases is very limited. That condition is still more rare in which a pulsating thoracic hernia of the purulent pleural effusion exists, the so-called empyema necessitatis. Many theories have been advanced to explain the pulsation of certain empyemas. Not one of them, however, seems to offer a satisfactory explanation. Cases of pulsating pleurisy, in which the fluid has been serum, have been reported. The pulsation generally occurs when effusion occupies the left pleural cavity, but in a few cases it has been observed in right-sided pleurisy. The high specific gravity of the effusion has been offered as an explanation of the pulsation; but in the case the report of which follows this was not the cause, as pulsation was equally distinct when the chest was filled with salt solution.

The explanation of empyēma necessitatis is probably as follows: As the result of long-continued pressure, a local necrosis of a portion of the pleura occurs; the pus, being no longer confined by this tense membrane, bulges out the soft parts which cover the chest, and finally, after forcing itself through the ribs, forms an external tumor. The muscles stretch, become very thin, and may gradually disappear, thus leaving the skin as the only covering of the hernia; and finally this latter structure may become gangrenous and complete perforation of the chest wall take place.

G. V. E——, aged thirty-seven. Brother died of pulmonary tuberculosis; family history otherwise good. No alcoholic, syphilitic, or rheumatic history. Five years ago pneumonia, followed by pleurisy, with apparently perfect recovery; at the same time fistula in ano, cured by operation. General health fairly good until December, 1895, when he noticed shortness of breath on exercise. This gradually increased, so that by the middle of January he was obliged to give up work. He had not been confined to bed, but felt that he was losing flesh and strength, suffered from slight cough, but there were no expectoration and no night sweats. About the middle of February he noticed a small, pulsating swelling on the chest wall, half-way between the left nipple and the middle of the clavicle. This slowly increased in size. Loss of flesh and strength continued, with increased difficulty in breathing. In May he was seen by Dr. Edward G. Janeway, who diagnosed pulsating empyema. A needle passed by him into the left pleural cavity withdrew thick pus. This was examined by Dr. Theodore C. Janeway, who found with the microscope tubercle bacilli, and a guinea-pig which he inoculated died two months later of general tuberculosis. Dr. Janeway recommended operation and sent him to the hospital.

Admitted to the surgical division, May 28, 1896. Temperature, 98° F.; pulse, 120; respiration, 32. Patient anæmic, poorly nourished. Considerable dyspnœa on exertion. On examination, there was seen on the anterior surface of the left side of the chest a swelling somewhat circular in shape, about four inches in diameter. There was marked pulsation in this swelling, and this was evident to the eye even at a considerable distance. On palpation it was so distinct that the impulse was similar to that of an aortic aneurism. Pulsation was synchronous with the cardiac impulse, and was more marked on expiration. The swelling was in greater part reducible by strong pressure. There was marked pulsation, both to sight and touch, of the intercostal spaces of the left side of the chest. There were flatness and loss of fremitus and of auscultatory signs over the entire left chest, except at the apex of the lung, where there was a tympanitic note. The heart was pushed to the right of the sternum, so that the apex beat was situated one and one-half inches to the right of that bone, and cardiac dulness extended three inches in the same direction.

Operation under chloroform: An incision two and one-half inches long was made over the eighth rib in the midaxillary line of the left side. The periosteum was reflected: the pleural cavity opened by a small puncture between the eighth and ninth ribs, and thick creamy pus allowed to run out slowly. The pus was so thick that it flowed out with some difficulty. There was no foul odor. When two quarts had been evacuated, a portion of the eighth rib, one and one-half inches in length, was excised.

The patient was then turned on the left side, and another quart or more of pus escaped, its egress being still further aided by elevation and depression of the patient. Irrigation with hot salt solution followed, which brought away thick masses of coagulated pus and fibrin. As the opening was not large enough to afford free exit to these masses, a corresponding portion of the ninth rib was excised. The internal surface of the pleura was covered throughout with a layer of membrane thicker than blotting-paper. Free washing with salt solution was not sufficient to dislodge the membrane, and therefore the surface of the pleura was thoroughly scrubbed with gauze sponges till the irrigating fluid came out comparatively clear. Two large drainage tubes and some strips of iodoform gauze were inserted for drainage.

As soon as the fluid was evacuated, the heart began slowly to return to its normal situation, and when the operation was completed the apex beat was felt midway between the sternum and left nipple. The pericardial sac could not at first be felt by the exploring finger, but at the close of the operation it was within reach.

In order to test whether or not the pulsation had been due to the character of the fluid, the chest was filled with salt solution, the opening being temporarily closed, when the pulsation returned as vigorously as before operation. Comparatively little shock followed, but there was considerable oozing from the wound.

May 29th, highest temperature, 99.25° F.; pulse, 90; respiration, 26. Much relieved.

May 30th, highest temperature, 100° F.; pulse, 100; respiration, 26. Profuse discharge from the chest.

During the following week the temperature ranged between 99.5° and 101° F.; pulse, 90 to 100; respiration, 24 to 30.

On June 3d the tubes were removed, the chest was irrigated with salt solution, and the tubes were replaced.

During the next fortnight irrigation was used every second day. Considerable discharge of pus.

On June 9th the temperature became normal, and did not again rise above 99.5° F. The pulse remained at about 80, and respiration between 24 and 30.

After June 18th, daily irrigation. Cavity contained forty-two ounces of salt solution. Daily discharge of pus, three to four ounces. Patient out of bed on June 13th. Rapid gain of strength, shortness of breath disappearing. As the patient desired to go to his home in the country, he was discharged on July 13th. The cavity at that time contained thirty-eight ounces. The discharge of pus was between three and four ounces in the twenty-four hours.

Pathologist's report by Dr. Thacher: Microscopical examination of sections of membrane: no structure—amorphous material. Microscopical examination of

smears from the pus: no tubercle bacilli found, no bacteria of any kind. Culture on blood serum resembles staphylococcus poygenes albus.

November 15th, Dr. George E. Titus, of Hightstown, N. J., writes that the progress of the case has not been satisfactory. The patient has lost rather than gained strength. His evening temperature is between 100° and 101° F.; pulse, 90 to 110. The lung is not expanding. I have advised him to return to the hospital for the purpose of undergoing either Estlander's or Schede's operation.

In this case the question at once arises: How long had the empyema existed? Was it the direct result of the pleurisy and pneumonia from which he had suffered four years previously, or was it of more recent occurrence (five months)? He claims that he felt perfectly well until December, 1895. If this is true, the onset at this time must have been insidious. If the empyema followed the pleurisy of four years previously, it is singular that his general health should not have suffered during this period, and yet the partial perforation of the chest wall certainly favors the longer duration of the disease. If the empyema is tuberculous, as seems probable, the five months' duration seems more probable than the four years', considering the condition of the patient during this period.

GANGRENE OF THE PENIS AFTER RITUAL CIRCUMCISION.

By A. BROTHERS, B.S., M.D.,

NEW YORK.

It is bad enough to lose a child from disease, but it is terrible to see a healthy, well-developed child sacrificed to a religious custom. A certain number of subjects succumbs yearly after having been subjected to the trivial operation of circumcision—chiefly from hemorrhage or sepsis—and only exceptionally are such cases exposed to the sunlight of publicity. The specialist in circumcision, or "mohel," is usually a pious man or "reverend doctor," and the religious element acts as a cloak in protecting him from the punishment or suits for damages to which midwives, dentists, or physicians would, under parallel circumstances, be exposed. As the case in point was certainly due to ignorance of the worst sort, and as the "operator" has tried to shift the blame to the doctor, I do not hesitate to publish the case, in the hope that it may add to the testimony favoring inhibitory or restrictive legislation in this particular kind of work. It may be of interest to state that the individual in question has had an experience of many years, which, instead of making him more cautious, has only tended to increase his sense of inflated vanity. He publicly boasts of his ability to dispense with medical assistance, and in the present instance coolly announces that "the doctor was at fault." Now for the case.

On October 2, 1896, I delivered Mrs. I—— of her third child, after an unusually easy labor. The baby was of the male gender, weighed eight pounds, and was normal in every respect. The puerperal week was uneventful, and on the ninth day I ceased making visits.

On October 10th the child was circumcised, and, as is customary in such cases, I was not invited to interest myself in the religious features of the case.

On October 12th—forty-eight hours after the operation—I was sent for, and for the first time was told the following story: On the night of the circumcision the baby bled so freely that the "mohel" (not the doctor!) was sent for. After stripping the child, he laid it on a table in a rather cold room, and worked over the baby from seven until eleven o'clock, before he could control the hemorrhage. After thus satisfying the family of his ability to get along without doctors, he departed. On the following morning (October 11th), although the child was cross, refused to nurse, and had fever, he pronounced everything all right. I saw the mother for a few moments that day, but, as she explained afterward, fear of my intruding into the "mohel's" domain restrained her from directing my attention to the facts concerning the baby. On the next day, however—October 12th—she was obliged to send for me. The baby was feverish, refused to nurse, whined continuously, vomited from time to time (occasionally with blood), and was distinctly collapsed. I was sent for to prescribe for the "baby's stomach," as the vomiting indicated to the nurse that the baby's stomach certainly was out of order and syrup of rhubarb had failed to give relief.

On looking at the baby I was struck with its appearance of profound collapse. The rectal temperature was 101.5° F. After eliciting the foregoing history, I proceeded to investigate the surgical aspect of the case. The abdominal wall protruded, on account of a distended bladder, which extended half-way up to the umbilicus. The penis presented an appearance which I have never seen before. The skin of the penis did not extend beyond a half-inch from the line of the abdominal wall. Anterior to this the organ was in a condition of dry gangrene, and presented a black, hard, cylindrical mass, about three-fourths of an inch in length. Constricting the gangrenous portion of the penis, I discovered a narrow strip of gauze, evidently saturated with some styptic. This was separated with difficulty from the tissues beneath, after division with scissors. No sign of the urethral orifice could be discovered. I began cutting away the charcoal-like tissue at the extremity of the penis for about one-eighth of an inch, until structures were reached presenting a sickly yellow appearance. Beyond this, healthy living tissue was met, which bled on being cut into. At this stage, a free discharge of the pent-up urine occurred—probably three or four ounces—and continued in a fine stream for nearly a minute. I ordered boracic-acid dressings for the wound.

The subsequent progress of the case was, briefly, as follows: During the night the child developed convulsions. Vomiting was incessant.

October 13th, rectal temperature, 103° F.; pulse, 160.

October 16th, temperature still ranged between 102° and 103° F. Vomiting ceased. Bowels loose. Child presented a more encouraging appearance. Gangrenous portion of penis was steadily growing smaller.

October 18th, stump of gangrene came away in a lump.

October 23d, a large abscess over the right scapular region was freely incised. Convulsions again made their appearance, but were kept fairly well under control with two-grain doses of potassium bromide.

From this time on the baby lost slowly but steadily. Nursing became more difficult. Vomiting appeared, later with blood. There seemed to be some swelling of the remaining portion of the penis from to time.

On November 15th the baby died of exhaustion, under the care of a fellow-practitioner.

I do not wish to be understood as opposing the ritual performance of circumcision, or condemning "mohels" in general. Under proper surroundings, I believe the rapid performance of circumcision to be attended with little more risk than the extraction of a tooth. Similarly do I know that there are many "mohels" who possess good judgment and discretion. Besides all this, the Jewish religion makes provision for certain classes of cases, in which postponement of the operation is allowed. Still, I believe that certain laws ought to provide for the punishment of "mohels" who wilfully neglect to call in the assistance of physicians in cases of hemorrhage which may require the

use of cautery, suture, or ligature, in the proper use of which they, as a rule, have not been instructed. Similarly it would do no harm if some supervising influence would result in teaching the majority of "mohels" the first principles of asepsis.

PNEUMONIA.

By J. C. McALLISTER, M.D.,

HIGHESVILLE, PA.

Inasmuch as you have recently published two leading articles on pneumonia, one of which spoke disparagingly of cold applications to the chest, I wish to submit the following report, wherein I attribute the good effects largely to the use of ice over the pneumonic area. While my experience in the use of ice has been very limited, yet all the physicians with whom I have talked and who have used it, report similar favorable results.

Mrs. H——, aged fifty, is of fair physical size and appearance, but does not endure sickness well. The

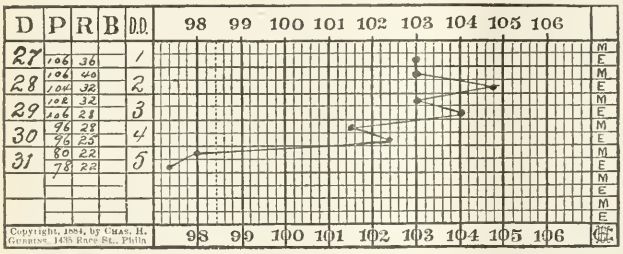

chart will show pulse rate, temperature, and respiration. These were taken at 9 A.M. and 5 P.M. of each day.

The following are notes taken from the nurse's record:

August 27th: "Came this evening. Patient has great pain in right side. Applied hot stupes. Vomits everything."

August 28th: "Dr. McAllister called at 9 A.M., and ordered ice applied to the patient's side. Ordered one-fortieth grain sulphate of strychnine every four hours, and one tablet Da Costa's heart tonic (glonoin, strophanthus, belladonna, and digitalis) every four hours. Bowels moved several times, for which were given powders of calomel, podophyllin, menthol, guaiacol, and eucalyptol."

August 29th: "Bowels move frequently. Much gas and distress in bowels. Ordered to use four to six drops of guaiacol, applied to inner surface of left thigh, every two hours, to rèduce temperature. At 6 P.M. perspired freely. Liquid peptonoids used as food."

August 30th: "Perspired very freely. Bowels still loose. Give one drachm of paregoric as often as necessary reasonably to control bowels."

August 31st: "Remove the ice from patient's side. Profuse sweating. Bowels move a number of times. Apply fly blister to side."

Diagnosis of broncho-pleuro-pneumonia made from general symptoms, pain, prune-juice expectoration, etc. The complicating diarrhœa was of a fetid character, and was very much like that of typhoid fever. The calomel and podophyllin were given in very small doses.

The prevention of consolidation of the lung and the speedy cure (five days), I attribute to the local use of the ice, as no other radical measures were taken, such as venesection or the use of veratrum viride, to jugulate the disease. There were no evils present attributable to the use of the ice.

A CASE OF CARBOLIC-ACID POISONING.

By W. W. KING, M.D.,

DAYTON, O.,

ASSISTANT SURGEON TO THE NATIONAL MILITARY HOME.

On Sunday afternoon, November 22, 1896, Edd. A—— (ward master of Ward 11), in the presence of several patients, poured into a small medicine glass about an ounce of a colorless fluid and swallowed it at a gulp. Immediately afterward he hurried up the ward to the water tank and rinsed his mouth out with water. He seemed excited and to two nurses who asked him what was wrong he stated that he had swallowed an ounce and a half of carbolic acid, mistaking it for morphine solution.

He now hurried over to my room, which was a short distance away, and informed me upon his arrival there that he had swallowed by mistake an ounce and a half of carbolic acid.

Patient seemed very much excited. There was a strong odor of carbolic acid in his breath, and the lips were white. He was asked to seat himself on the sofa and I immediately prepared and injected into his arm a hypodermatic of apomorphine hydrochlorate, one-tenth grain. Soap being the only alkali present at the time, a solution of that was made and given. Dr. B. Jelland entered my room about this time and was asked to bring an alkali. He had a supply of sodium bicarbonate and bismuth subnitrate in his room across the hall. They were brought and quite a quantity of each was given. Patient at this time had considerable difficulty in swallowing. Five minutes having elapsed and vomiting not having occurred, the dose of apomorphine was repeated. No emesis followed. The patient's face, at first flushed, soon became pale and slightly cyanotic. About five minutes after I first saw him he had tonic spasms of the voluntary muscles with muttering delirium; he did not at this time seem conscious of his surroundings.

Tonic rigidity of muscles preventing deglutition, a male urethral soft-rubber catheter was passed through the nostril into the œsophagus, a Davidson syringe attached to the catheter, and a quart of milk pumped into the stomach.

Pallor became markedly increased and the surface of the body cold to the touch. Respirations labored; pulse weak and intermittent; pupils contracted. Patient did not at any time complain of pain.

Fifteen minutes after entering my room he was carried to a ward near by and placed in bed. Bottles of hot water were placed about him and he was well covered with blankets. Nitroglycerin, one-fiftieth grain; strychnine sulphate, one-twentieth grain; tincture of digitalis, ten drops, were given hypodermatically. Whiskey was given freely hypodermatically, the patient having been addicted to constant use of alcoholic beverages.

About thirty minutes after the ingestion of the poison he was catheterized and a half-ounce of urine was withdrawn. The urine had a light color and a very distinct odor of carbolic acid. Fifty minutes after I first saw the man respiration ceased. The pulse still beat feebly. Artificial respiration was resorted to, and in about a minute he again commenced to breathe and continued to do so thirty minutes longer, at which time respiration ceased and the pulse could not be detected. Artificial respiration was kept up ten minutes after death. Autopsy was not allowed.

On investigation we found that the man had swallowed one ounce of pure carbolic acid, he thinking at

the time that it was dilute alcohol which he was in the habit of taking.

I wish to call attention to the fact that in this case apomorphine had absolutely no emetic effect. This was probably due to the fact that the carbolic acid already absorbed had paralyzed the vomiting-centre in the medulla.

Several months ago I had occasion to use apomorphine in a case of chloral poisoning, the patient at the time being in a stupor. It was given in one-tenth-grain doses three times hypodermatically, doses being about five minutes apart. No vomiting was produced.

In my opinion apomorphine as an emetic is unreliable, and in neurotic poisoning, when the drug or drugs taken produce stupor I think apomorphine utterly worthless. Valuable time is often lost while we await its emetic effect. In the carbolic-acid poisoning case if I had not depended on the emetic effect of the apomorphine, I would in all probability have given the nearest alkali and then hurried after a stomach tube. I should probably have been able to wash out the stomach before tonic rigidity became marked. As it was, the jaws soon became firmly closed, and fifteen minutes after I first saw him the introduction of a soft-rubber catheter into the œsophagus (with the intention of pumping a solution of Glauber's salt into the stomach) so interfered with respiration that it was soon withdrawn.

APPEARANCE OF ZOSTER AND SYPHILIS IN THE SAME SUBJECT.

By J. ABBOTT CANTRELL, M.D.,

PHILADELPHIA, PA.,

PROFESSOR OF DISEASES OF THE SKIN IN THE PHILADELPHIA POLYCLINIC AND COLLEGE FOR GRADUATES IN MEDICINE, DERMATOLOGIST TO THE PHILADELPHIA AND FREDERICK DOUGLASS MEMORIAL HOSPITALS.

The simultaneous appearance of a herpes zoster and a syphiloderma in the same individual is so likely to lead one into error that, such a condition having arisen in one of the clinical subjects of the Philadelphia Polyclinic, I venture to record it.

These affections appeared in a woman who presented herself for treatment on February 26, 1896, and, according to her statement, were of only two weeks' duration. Examination of the diseased areas revealed groups of vesicles scattered at irregular intervals upon or around the left shoulder and corresponding portion of the chest. She stated that for about seven days previous to the appearances of these little "bladders," as she termed them, she suffered from the most extreme pain, which did not confine itself to the site of the present lesions, but radiated all through the contiguous areas. This pain was of a neuralgic nature, varying greatly in intensity, at times almost passing endurance, and affecting her in a manner that almost drove her to distraction. Being paroxysmal, it gave her moments in which life seemed to her to be at least tolerable, but in another moment the excruciating pain that was induced was almost unbearable, causing her to walk to and fro through the limited area of her room, with little if any clothing upon the diseased part, as every weight seemed to aggravate the degree of discomfort. Upon the appearance of the vesicles, she says, the pain decreased in some degree, but was still disagreeably uncomfortable, though more of an incessant character, being more like the pain of a dull toot ache.

The lesi ns at the time of her appearance at the clinic were situated upon the left side of the body, encircling the chest, and arranged with the usual manner of grouping. In addition to the lesions seen upon the trunk, there were numerous groups situated upon the external aspect of the left arm and covering its shoulder, but not presenting any contamination of the axillary region. These lesions were all characteristic of the condition, being grouped in the majority of instances with scattering vesicles in rather a direct line along the course of the intercostal nerve, with groups and discrete lesions over the remaining territory. Some of the lesions situated upon the arm had ruptured, possibly from rubbing of the clothing, and were covered with a blood-stained crust, which revealed upon removal some discharge of a purulent material, while those lesions found upon the upper part of the shoulder presented a denuded appearance with the discharge of a sero-purulent character without the formation of a crust. The after-effects were of rather a mild character compared with the previous intense symptoms, but nevertheless the pain which had been the forerunner and an acccompaniment of the vesicular manifestation remained to some slight degree for a period of at least two or three weeks after the entire disappearance of these lesions. During this latter period she was permitted to sleep the entire night, a privilege which was not enjoyed since the seven days previous to the appearance of the zoster.

The foregoing history presents nothing unusual in the history of a herpes zoster, but the peculiar and interesting portion of the case was witnessed in the intrascapular region of the right side, in which a collection of lesions were massed in one group, about midway between the upper and lower angles of the right scapula and on a line with the affection of the opposite portion of the body. These lesions were of a tubercular nature but of a small size, being grouped in a manner similar to the aggregation of zoster vesicles, and for a time it was rather difficult to say whether they were the papular stage of a zoster or whether another disease was present. Upon closer inspection, zoster was entirely differentiated from the diagnosis, because of the absence of the peculiar halo or erythematous redness, which was well-marked upon the lesions occupying the corresponding portion of the opposite side, the hard character of the lesions, the entire absence of pain to the touch, its non-superficial attack, and the amount of induration with the depth to which it had extended.

The color of the lesions was possibly suggestive of no particular disease, as we are all aware of the manifold colorations which the syphilitic process may assume, being in the one instance of what may be termed a raw-ham color, while at another time the coppery hue may be discernible, or at still other times gradations of tints varying from positive redness to bluish redness may be witnessed. The lesions under consideration, as well as the surrounding area, were of a darkish brown color, with no tendency to ulceration or discharge of any character, nor did they present any subjective symptoms of itching or pain—in fact the history, as far as it was obtainable from the patient, did not give any clew to a diagnosis; but she positively stated that the lesions were not there before the present zoster, but had appeared coincidently with it, at somewhat a later period than the attack of zoster. Close inspection revealed that instead of being papules the lesions were tubercles, and, being closely aggregated without discharge or pain, with the depth to which the patch was affected and a peculiar tint which we could not associate with any other disease, they drew my mind to a non-ulcerating tubercular syphiloderm, which indeed the affection proved to be.

There is no doubt in the mind of the writer that such complications may arise, just as well as any other disease may simulate those affections in which it is difficult to make a correct diagnosis without deep inquiry, and for that reason this case is placed upon record.

315 South Eighteenth Street.

Progress of Medical Science.

The Immunizing Power of Nucleohiston and of Histon.—An experimental inquiry into the immunizing power of nucleohiston and of histon conducted by Novy (*Journal of Experimental Medicine*, November, 1896, p. 693) in the hygienic laboratory of the University of Michigan has shown that neither of these substances affords protection against a separate and subcutaneous injection of tetanus toxin, diphtheria toxin, hog-cholera bacillus, or anthrax bacillus. Mixtures of nucleohiston, and both tetanus toxin and diphtheria toxin admixed with nucleohiston, lose their specific toxic action, the second much more rapidly than the first. Animals that survive such inoculations are, however, not immune. In a mixture of nucleohiston and anthrax bacillus the latter is unaffected, even after the lapse of several days (eleven). The destruction of specific toxins in a solution of nucleohiston, though in part due to the sodium carbonate present, is probably due chiefly to the nucleohiston. In a mixture of histon and diphtheria toxin the latter is destroyed in a few minutes. This action is due in part if not wholly to the acidity of the histon solution. Similar mixtures of closely related bodies, serum globulin or albumoses, in Witte's peptone yield analogous results. The animals that survive such injections are not immune. Histon does not destroy the tetanus toxin so readily as it does the diphtheria toxin. Histon possesses decided and marked toxic properties which are not due to the hydrochloric acid present.

Paralysis of Central Origin Following Diphtheria.—Dr. Manicatide (*La Médecine Moderne*, November 7, 1896) distinguishes the following groups of paralysis following diphtheria, or, better, the different terminations of the toxin of the bacillus of Loeffler: 1. A limited group at present. Paralysis due to muscular lesions, without alteration of the nerve substance, to which the studies of Hochhaus bear witness. 2. A group comprising all paralyses due to neuritic lesions: common paralysis, classic and those more rare, which take the form of pseudo-tabes or ascending paralysis. The lesion is always found in peripheral, centrifugal, or centripetal (motor or sensory) nerves. 3. Paralyses with medullary lesions, whether of the gray matter, as in certain cases of persistent muscular atrophy (Oertel, Déjerine), or of the white matter, as in certain cases of the locomotor-ataxia form or sclerosis in patches (Bikeles, Preisz, Henchen). These lesions have been produced experimentally by the Crocq brothers, Hallion, and Enriquez. 4. Paralysis of central origin; cerebral, ordinarily hemiplegic, due to embolism, a hemorrhage from cardiac or vascular lesion, and these have been made the special object of study. The diphtheritic toxin can also have a direct action upon the cerebral nerves, as has been observed by C. Ceni in his experiments. A case of paralysis in an adult clearly due to diphtheritic encephalitis has not yet been found. The degenerative lesions and atrophies of cerebral cells found by Pernice and Scagliosi are disseminated, and do not produce appreciable functional troubles. It is but rarely that one can observe a typical case of lesion purely neuritic, medullary, or cerebral. More often these lesions are combined, neuritic and medullary, cerebral and neuritic, neuritic and muscular, etc. The prognosis and treatment vary according to the nature of the lesion and its importance.

The Human Hand.—In a paper upon the clinical significance of the changes noted in the hand, Dr. A. S. Wohlmann gives the following *résumé* of the various conditions of more or less rare occurrence in which characteristic alterations are noted: 1. Paget's disease (osteitis deformans). The cranium and long bones are the parts usually affected, and though the hands sometimes show changes, these are hardly diagnostic and are very rare. 2. Acromegaly (of Marie). The large size of the hands is due to the excessive development of all the tissues. There is no appreciable increase of length, only of width and thickness, earning for the hands the epithets of "battledore" and "spade-like." The wrists are about normal. The nails are somewhat flattened, small, and longitudinally striated. 3. Hypertrophic pulmonary osteo-arthropathy. The carpo-metacarpus, the hand proper, is about normal in size; but the fingers are enormously enlarged, the bulbous terminal phalanges being especially prominent. The nails are curved and striated, reminding one of the beak of a parrot. There is great enlargement of the wrists. 4. Myxœdematous hands may at first sight be mistaken for either 2 or 3: but it will be seen that the skin of the other parts of the body is involved and it is adherent to the deeper structures. 5. Vasomotor paralysis of the extremities. A few rare cases have been set down to this cause, and may somewhat resemble the foregoing; the presence of subcutaneous hemorrhages may clear up the diagnosis. 6. The hands may exhibit marked changes in rickets, which in rare cases may simulate some of the former diseases; but an examination of the rest of the body will generally readily afford the data for a diagnosis. 7. In leontiasis ossea (Virchow) the hands may be affected; but for diagnostic purposes the changes are unimportant. 8. Nodosities of the fingers have been noted in connection with dilatation of the stomach.—*The Bristol Medico-Chirurgical Journal*, June, 1896.

Serum Therapy in Leprosy.—Dr. Carrasquilla, of Bogota, says the following changes are produced. 1. It restores sensation, more or less rapidly, according to the extent and gravity of the peripheral nerve lesions. 2. It decolorizes the maculæ, without entirely obliterating them; they desquamate abundantly. 3. It makes the œdemas disappear rapidly in some cases, slowly in others; the skin shrinks, becomes wrinkled, and returns to its physiological condition when the œdemas have disappeared. 4. The tubercles become smooth and soft, and disappear by absorption, desquamation, or suppuration, leaving traces at their sites. 5. The ulcers, after suppurating freely, cicatrize with amazing rapidity and leave the skin healthy. 6. The scars of old cicatrized lepromes grow pale and tend to become level with the surrounding skin. 7. The ulcerated mucosæ begin to cicatrize, decolorize like the skin, become sensitive, and the tubercles vanish. 8. The face becomes dry and entirely loses its leonine expression, when the œdemas and tubercles disappear and it becomes decolorized. 9. The appetite returns and so does sleep; the mind is gladdened, contentment takes the place of profound despair and depression of spirits, hope returns. 10. From the first injection of serum the morbific action of the leprabacillus ceases, because from that day on no new manifestation of the disease develops. "I have treated fifteen patients up to the present time, and in all, without exception, I have observed this fact, which I deem fundamental and decisive, since it reveals that the remedy acts directly and immediately upon the cause of the disease, and this is confirmed by the return of sensibility." To obtain the serum a leper is bled and with the serum derived a goat is inoculated. After several days the animal is bled from the jugular vein and the serum is preserved in flasks. Trial is first made on a guinea-pig to make sure that no septic matter is present.—*New Orleans Medical and Surgical Journal*, November, 1896.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

New York, January 30, 1897.

THE TREATMENT OF SYPHILIS BY INJECTION.

SINCE intravenous injections of cyanide of mercury have come up in the treatment of the severer manifestations of syphilis threatening such organs as the eye, the question of the injection method has become somewhat complicated. Formerly one was called upon to decide whether the injected mercurial should be of the soluble or of the insoluble kind. Now the decision must be made between intravenous and subdermic methods. It is no new thing to inject remedies directly into the veins, and even mercurial preparations, notably the bichloride, were long since used in this manner in certain septic and other states.

The tardy and uncertain action of mercury when given by the mouth or by inunction, in certain severe and obstinate syphilitic manifestations, especially when vital or important organs are threatened, has led investigators to pursue their search for better means of introducing the remedy so as to secure more speedy effects. This resulted in the introduction of the subcutaneous and subsequently of the intravenous method.

For the latter it is claimed that advantages are offered which offset the dangers of introducing air into the vein and of causing embolism, etc. One of the advantages claimed by Dr. Jéhin-Prume[1] is that stomatitis is rarely if ever produced. In an experience covering two thousand injections, he saw this complication produced but twice, and each time in a slight degree.

The conclusions this writer has drawn are that intravenous injections should be made only in the severe forms of syphilis, in which an immediate result is desired; when other forms of treatment have given little or no result; when other methods of application have not been accepted by the patient.

They should not be made when the venous system is but little developed, or in patients suffering from cardiac affections, or in patients with disorders of the vascular system—arteriosclerosis, varices, etc.

The syringe and needle must be kept sterile, and great care is required to exclude all air before injecting the solution, which contains one gram of the cyanide of mercury in one hundred grams of water. The maximum adult dose is given as one centigram, or the contents of a syringe holding one cubic centimetre.

Much has been written concerning the relative value of the soluble and insoluble mercurial preparations for hypodermic use, and each method has its ardent advocates. Surprising results have been reported from both methods in equally grave instances of syphilis. The tolerance shown by patients for the weaker solutions of sublimate has led Dr. Irsai to employ solutions of from three to five per cent., and during the past two years he has treated ten cases of severe syphilis of the larynx, giving from seven to ten injections in each. There was no instance of stomatitis, and only once or twice any salivation. An interesting report of a case is made by Horowitz,[1] which would go to show that in syphilitic endarteritis with nutrition changes in the brain or multiple gummata, inunctions may fail because the mercury does not penetrate to the blood current, examination of the urine showing that the mercury is not being absorbed. Stopping the frictions and giving sublimate by deep injection into the muscular tissue brought about speedy relief of the distressing symptoms in the case noted.

Experiments carried out upon animals in Ludwig's laboratory, in Vienna, have shown that mercury penetrates the various tissues in a very unequal manner, and thus is explained the slight effect often obtained in spinal-cord alterations and syphilis of the cornea.

The chief objections usually raised to insoluble preparations are the risks of cumulative effects and the inability to cut short the absorption when stomatitis, diarrhœa, or other signs of intoxication develop; the dangers of abscess formation, indurations, and pain. Yet, in spite of these drawbacks, these preparations would seem to hold the first place in the injection treatment of the present day. Their action is rapid, intense, and sure, and with proper antiseptic precautions they need not occasion fear of abscess, for the great majority of cases. Dr. Thibierge gives, in *La Presse Médicale*, October 17, 1896, the following *résumé* of the opinions held upon the question by those who have recently communicated their views to the Paris Dermatological Society: Injections of calomel are indicated in syphilitic manifestations which are severe by reason of their localization, their rapid progress, their resistance to other methods of mercurialization, their recurrences; they are also indicated each time that there is urgent necessity to establish rapidly and upon a certain basis the diagnosis of a lesion suspected of being of syphilitic nature. Personally, he thinks gray oil preferable to calomel for some cases.

One of the most recently proposed preparations is that of Rille—double hyposulphite of mercury and potassium, one and one-fourth grams dissolved in ten grams of distilled water. Of this a Pravaz syringeful is injected every five days. Although the injections are said to be quite painful, the results were satisfactory to the experimenter in the twenty-eight cases in which he employed the preparation.

FATAL HEMORRHAGE FROM A GASTRIC VARIX.

The differentiation between hæmatemesis and hæmoptysis, while at times simple and easy, is at other times quite the reverse. Important differential points are the mode of ejection, the appearance and color of the blood, and the presence of air or of food particles, in conjunction with a knowledge of the existence of disease of stomach or lungs. Hemorrhage from the stomach may be due to one of various causes, the most common of which are ulceration, carcinoma, aneurism, and cirrhosis of the liver. Ulceration is likely to be attended with localized pain, general anæmia, and excess of hydrochloric acid in the gastric juice. The positive recognition of carcinoma demands the demonstration of a tumor, although the peculiar cachexia and a deficiency of hydrochloric acid in the gastric juice have collateral significance. Fatal hæmatemesis may follow rupture into the stomach of an aortic or other aneurism whose existence may not have been suspected during life. When gastric hemorrhage is dependent upon cirrhosis of the liver the diagnosis must be based upon the size of the liver, the enlargement of the superficial abdominal veins, the presence of ascites, and the existence of hemorrhoids, together with various symptoms of gastro-intestinal derangement and a typical hepatic facies. Such hemorrhage may take place from numerous small vessels in the form of a general oozing, or it may occur freely from a single large and dilated vessel, or a congeries of such vessels. Sometimes fatal hemorrhage takes place in cases of cirrhosis of the liver from rupture of a varix of this kind in the œsophagus.

At a recent meeting of the Clinical Society of London, Lancaster[1] related the case of a married woman, thirty-six years old, who had felt badly for several weeks, but without definite symptoms, until she suddenly vomited about two pints of blood. Several days later she again vomited a similar amount of blood. There had been no abdominal pain or other symptom of indigestion or of peritonitis. The woman was extremely weak and pallid, and presented the signs of profound anæmia. There was no history of alcoholism or of syphilis. Gastric ulceration was diagnosticated and rectal feeding instituted. Slight improvement appeared to take place, but on attempting one day to turn in bed the woman fainted. Thereafter, in spite of active treatment, the patient continued to run down, dying finally fourteen days after the first hemorrhage. Upon post-mortem examination there was found a varicose condition of several branches of the gastro-epiploic veins in the great omentum and gastric submucosa. The largest of the gastric varices presented on its upper surface a small, circular, smooth-edged aperture about the size of a pin's head. The left kidney and the left adrenal were wanting. In the discussion that followed the reading of the report of this case, the suggestion was offered that if the condition could have been diagnosticated, operation would have been indicated.

Barker (*Lancet*, December 5, 1896, p. 1,583) has reported a series of seven cases of gastric ulceration, all in women, in which operation with suture of the perforation was undertaken, recovery resulting in three. He adds a brief reference to two other cases, occurring in males, in one of which recovery seemed assured, while in the other death took place.

[1] Lancet, October 31, 1896, p. 1,228.

AGAIN THE DIPLOMA MILL.

It is with humiliation that we feel called upon once more to appeal to a sister State in the West to remove a stain from her banner. Communications have been received from many sources, not only here but in Canada, calling our attention to the circulars sent out by the Wisconsin Eclectic Medical College of Milwaukee, with correspondence department in the city of Chicago.

The offer, signed by Fred. Rutland, Ph.D., M.D., places a diploma at the disposal of any one who will pay $35, "all inclusive." The circulars seem to be sent largely to druggists, who are hoped to have aspirations to a profession which "runs side by side with that of pharmacy." It would seem too bad if, in face of the efforts made by the Illinois State board of health and the desires of all reputable physicians the country over, we should approach the new century with this blot still upon American medicine. The vast importance of making a United States diploma respected in all parts of the world should arouse those in authority to unusual effort at once. A State examination in every part of the country, ignoring for the time being every medical-college diploma, is the first step toward the abolition of these disgraceful clap-trap schemes of unscrupulous pretenders.

Rutland and his wife, who poses as the secretary of the "college," are the only members of the faculty who can be found to have any existence, according to investigations recently carried on at the seat of learning.

The president has titles of distinction. It is said that he claims to be a late surgeon and medical officer of the Wagga-Wagga district of the mounted police of South Wales. If they would only come over and take their lost surgeon home! Why stay in Wisconsin when he can have his Wagga-Wagga? And still Great Britain is the first to blame us! He is also a member of the National Union Medical Society of Chicago. Now, in the name of all that is good, will not a member of this society, if there is another member, see that steps are taken to expel Professor Rutland for conduct unbecoming a gentleman? If there is no other member, we should certainly expect him to have decency enough to expel himself at the very next meeting.

A Momentous Question.—A dentist in London has written to *The Lancet* to ask if it would be proper for him to extract a tooth from a patient who had been anæsthetized by a homœopath. The question has staggered even such expert medical casuists as the editors of *The Lancet*, and they suggest that it be referred to the British Dental Association.

News of the Week.

The Plague in Bombay and Kurrachee shows no signs of abatement. According to the official returns up to January 18th, there had been 3,636 cases and 2,592 deaths from the disease in Bombay, and 543 cases with 498 deaths in Kurrachee. It is believed, however, that these figures are far from correct, many of the cases being returned by the native physicians under other names. There has been a great apparent increase in the number of deaths from typhoid fever and malaria, and it is said that many cases of plague are returned as of some other disease through ether ignorance or a desire to spare the family a visit from the sanitary authorities. The *Times of India*, basing its estimate upon the number of deaths which have occurred in Bombay in excess of the average death rate for the last five years, which it thinks may safely be attributed to the plague, says that the disease has caused 9,835 deaths since its presence in Bombay was first officially recognized. Great alarm was caused in Marseilles last Saturday by the occurrence of nine sudden deaths in one street, which rumor attributed to the plague, but which the authorities asserted were due to pneumonia. There was also a report, which was later shown to be false, that a plague ship had arrived at Hamburg.

Obituary Notes.—Dr. William S. Roland, of York, Pa., died on January 23d, at the age of eighty-three years. He was a graduate of the medical department of the University of Pennsylvania in the class of 1835.—Dr. Ellen C. Leggett, the wife of Dr. Charles P. Leggett, of Flushing, L. I., died on January 17th. She was graduated from the Woman's Medical College of the New York Infirmary in 1873.—Sir Isaac Pitman, who arranged the system of shorthand writing in nearly universal use, died in London on January 24th, at the age of eighty-four years.—Dr. Richard J. Hall, formerly of this city, died in Santa Barbara, Cal., on January 23d, after a brief illness. His death was the result of a surgical operation for appendicitis. He was born in County Armagh, Ireland, forty-one years ago. He was graduated from Princeton University in 1875, and from the College of Physicians and Surgeons, New York, in 1878. He was house surgeon at Roosevelt Hospital, and then studied at Vienna. On his return he began the practice of surgery in this city, being associated with the late Dr. Sands. Ten years ago he lost his health through lung trouble, and went to the Pacific coast. There he almost entirely recovered, and built up a large practice in Santa Barbara. A widow and two children survive him.—Dr. Frederick M. Turnbull died at Boston, on January 16th, after a protracted illness. He was graduated from Jefferson Medical College, and had devoted himself to neurology.—Dr. Olive Dewey Aldrich, a graduate of the Woman's Medical College, died of pneumonia at her home in Philadelphia, on January 11th.—Dr. Jacob Reed, formerly of Philadelphia, died of pneumonia, on December 15th, at Colorado Springs, Col., whither he had gone twenty-three years ago on account of pulmonary tuberculosis. He was the founder of the El Paso County Medical Society and a member of the Colorado State Medical Society.—Dr. Joseph S. Brewer died on January 25th, at No. 270 West Ninety-sixth Street, of Bright's disease. He was forty-two years old. Dr. Brewer was born in Cortland, N. Y., and was a graduate of Cornell University and Bellevue Hospital Medical School. He was for several years house physician at the Vendome Hotel. In June last he married the actress, Mrs. Marion Singer-Atwood. Being in poor health, he devoted much time to travel. He is said to have left quite a large estate, much of which goes to a hospital in Cortland.

Dinner of the Alumni of Charity Hospital.—The seventh annual dinner of the Society of the Alumni of the Charity Hospital was given at the Hoffmann House, Wednesday evening, January 27th. The following gentlemen responded to the toasts of the occasion: Drs. George B. Fowler, R. W. Taylor, Hon. John W. Goff, Drs. W. L. Bauer, P. F. Mundé, George F. Shrady, E. D. Fisher, D. B. Delavan, and L. W. Hotchkiss.

Hebrew Sheltering Guardian Society of New York.—Prof. Carl Beck, president of the medical board of this institution, writes: "In your remarks upon the affairs of this institution in your valued issue of January 16th, you assume that the consulting medical board has 'meekly submitted to insult' from the board of managers. This is not the fact. The medical board, on tendering its resignation to the president of the board of managers, received an apology and the tender of absolute supervision and direction of all medical affairs of the institution. We disclaimed responsibility of the report in the medical press, mainly to show that we did not criticise our predecessors."

Action of the Health Board against Rear Tenements.—The referee appointed in an action brought by the board of health to compel the destruction of two rear tenements has filed a report sustaining the board in every particular. The testimony clearly proved that the tenements were unfit for human habitation, and that they were not reasonably capable of being made fit for human habitation. It also showed that the death rate was 45.87, against an average of 24 for the city. The defendants pleaded the unconstitutionality of the act, but the referee assumed the contrary, and the case was tried upon its merits. Should the act be sustained by the court when the referee's report comes up for approval, the board of health will proceed immediately against about fifty more rear tenements.

Following a Doubtful Example.—It is reported that Health Commissioner Starkloff, of St. Louis, will recommend to the board of health of that city that pulmonary tuberculosis be declared infectious.

An Epidemic of Measles is reported to exist at Shamokin, Pa., upward of two hundred cases having been reported up to January 19th, when the epidemic manifested no sign of abating.

Philadelphia County Medical Society.—A stated meeting of the Philadelphia County Medical Society was held on January 13th in the upper hall of the College of Physicians, the president, Dr. J. C. Wilson, in the chair. Dr. T. S. K. Morton demonstrated an electric headlight, provided with a reflector and with an extremely simple and ingenious switch; and also a small light for introduction into cavities and the like, kept constantly cool by a current of water flowing around the glass bulb, which is in turn surrounded by a second glass bulb. Dr. Morton presented a woman from whom he had excised the head of the left radius for the correction of a dislocation of eight months' standing, with perfect return of mobility and restored function. He also presented a young man in whom skin-grafting after the method of Thiersch had been resorted to successfully to promote the healing of a large wound, extending from the malleoli to above the knee, and resulting from a burn with scalding water. Amputation was recommended, but the patient declined operation. The grafting extended over a period of almost a year. Dr. J. P. Mann read a paper upon the treatment of club foot, in which he spoke warmly of manipulative and mechanical treatment and tenotomy. In an experience dealing with some five hundred cases of club foot, he had seldom if ever found operation upon the bones necessary.

The Medical Students in Paris number no less than 5,445, of whom 1,280 are foreigners and 27 are women.

Competing Medical Meetings.—The meeting of the British Medical Association in Montreal in August next, besides drawing away from attendance at the International Congress in Moscow, will also, it is asserted, interfere with the Philadelphia meeting of the American Medical Association. The Chicago correspondent of the *British Medical Journal* writes that, while there will doubtless be a large attendance at Philadelphia, Montreal is certainly going to see many American practitioners at the time of the British meeting. "The visit to that city alone (which, by the way, is quite as easily and comfortably reached from the populous northern and western States as Philadelphia), the fact that a new body of professional brothers can be seen in working order, and can become known socially and measured intellectually, and that teaching from new sources may be obtained, and the knowledge that this is to be the first of its kind, and that it will to a very large extent take the place of the Moscow meeting, will turn much attention toward Montreal. Let it not be understood from this that there is any evident feeling of opposition to the Moscow congress, or that any sense of strife has been engendered. It is simply a question of, first, distance (in the one case a distinguished meeting is brought close to home, in the other it is carried far away); second, a common language; and third, the very fact that, although denominated the meeting of the British Medical Association, yet, after all, and in point of breadth and value, it will be regarded, as it will quite be in fact, as having the value and elements of an international assembly. Then there is another factor which will turn many toward Montreal, viz., the open hostility to the American Medical Association in Boston and New York. Of course, these gentlemen would not attend the Philadelphia meeting. They will, however, go to Montreal, and will very decidedly help to swell, not only the members from this side, but their individuality and reputation will lend much to the interest of the occasion, and their going will carry many others. In Chicago and vicinity we look for a division of interest and attendance."

Philadelphia Pediatric Society.—The first stated meeting of the recently organized Philadelphia Pediatric Society was held on January 12th and was largely attended. Dr. F. A. Packard exhibited a boy, of about thirteen years old, who presented marked dilatation of the stomach, probably of congenital origin. Dr. Alfred Stengel exhibited a child, about six years old, presenting weakness and wasting of the lower extremities, with defective station and steppage gait, without sensory involvement, but with increased knee jerks, in the sequence of arsenical treatment for the relief of chorea. The dose of the Fowler's solution used had been gradually increased from three to ten drops thrice daily. The case, though presenting elements of doubt, was concluded to be one of arsenical neuritis. Dr. Charles S. Potts demonstrated a case of progressive neural atrophy (peroneal type) in a young man about eighteen years of age. Dr. M. H. Fussell exhibited two cases of cretinism, one in a child of seven years and the other in a boy of twelve, in both of which marked general improvement and increase in stature had followed treatment with thyroid extract. Dr. H. B. Carpenter also exhibited a case of cretinism in a child, three and a half years old, in which a like result followed similar treatment. Dr. George Woodward presented a communication entitled "The Chemistry of Colostrum Milk." The new society has apparently entered upon a very prosperous career and promises to take a conspicuous place among the scientific bodies of the city.

Duty on Scientific Books.—Among the works in the English language which are admitted free of duty are "scientific books and periodicals devoted to original research," and there has been some doubt as to the interpretation of this clause. The treasury department has recently issued a circular to the collectors of customs in which it is said that certain books have been admitted under a too liberal construction of the law, and the customs officers are notified that the words "scientific books and periodicals devoted to original scientific research" relate to new discoveries in the field of science, and do not include text-books, compilations, and discussions of scientific subjects already understood. It is still uncertain how much original matter will entitle a book to free entry as one "devoted to original research," but a case which has come up recently in Philadelphia concerning the importation of a medical work has been appealed to the circuit court, and may bring about a settlement of the question.

A Strike of Doctors.—At Yarmouth, England, the physicians demanded higher fees from the benefit associations than they had been paid, and a limitation of the classes of patients to be attended at club rates. The physicians struck. The associations combined, and, finding that they provided $10,000 worth of business a year, established a central office of their own, hiring a doctor from out of town to manage it. The strike failed.

Memorial for a Permanent Census Service.—The Michigan State board of health, Dr. Henry B. Baker, secretary, has passed a resolution urging the passage by Congress of a bill, introduced by the Hon. Carroll D. Wright, for the establishment of a permanent census service, on the ground that great advantage would result therefrom to the sanitary interests of the country.

Dr. Cullingworth, who had such a disagreeable experience with a charity patient who sued him for malpractice, has received through subscriptions from his professional brethren a sum sufficient to cover fully all the expenses of his trial. He has furthermore been elected president of the London Obstetrical Society as a testimony of the esteem in which he is held by his associates.

Male versus Female Nurses.—The superintendent of the Kings County Hospital does not approve of male nurses, and proposes to discharge all in the hospital and place the male wards in the charge of women. He is reported to have said that there never was a man born fit to be a nurse, that men are not quiet and sympathetic but rough, and apt also to be untidy.

The Greater New York Health Board.—Health Commissioner Emery, of Brooklyn, has sent a communication to the Greater New York Commission with reference to the health-board provisions of the proposed charter, in which he enters emphatic protests, first, against making the head of the department of health a board composed of four members, and second, against the discrimination which is here made against the members of the medical profession by the provision that under no circumstances shall a physician become the president of such board. He also suggests that in the presence of great and imminent peril, such as is liable to arise from impending or existing pestilence, it is unwise to limit to $80,000 the extraordinary expenditures of the health department. He thinks the provisions of the charter enforcing a certain method of disposition of garbage, ashes, and street refuse are very unwise, for in this way the hands of the health board would be tied, and no matter what better and cheaper methods might be devised in years to come, they could not be adopted by the board until after an amendment to the charter had been obtained from the legislature.

Suit for Damages for Ante-Natal Injuries.—It is stated in the *Medical Standard* that a suit has been instituted against St. Luke's Hospital of Chicago by Thomas Edwin Allaire, through his mother, which is reported to be the first case of its nature in this country. In February, 1886, three days before the birth of the plaintiff, his mother, Ada A. Allaire, was injured in an elevator at the hospital. When the plaintiff was born, it was found that his left leg was drawn and the muscles were contracted. The limb is three inches shorter than the other one, and he will be always lame. For these injuries received before his birth the youth wants $50,000 damages.

The Adelaide Hospital.—The physicians in Adelaide who were ousted from the public hospital there, their places being filled by Dr. Leith Napier and another doctor from London, are no more than human, and doubtless, therefore, are not mourning over the trouble Dr. Napier has got himself into. Within a month after he commenced his duties in the hospital, he performed a Cæsarean section on a woman, who died in consequence. According to the testimony of the husband and relatives of the patient, no authorization for the operation had been granted, either by the woman or her husband, and it is sought to bring a charge of manslaughter against the operator. There has been so much said about the matter that the legislative council has appointed a special committee to investigate the management of the hospital under Dr. Napier and his colleague.

Montgomery County (Pa.) Medical Society.—The annual meeting of the Montgomery County Medical Society was held on January 13th, at Norristown, Pa. The following officers were elected for the ensuing year: Dr. J. W. Graff, of Harleysville, *President;* Drs. J. R. Care and C. H. Mann, *Vice-Presidents;* Dr. H. H. Whitcomb, *Recording Secretary;* Dr. J. K. Weaver, *Corresponding Secretary;* Dr. S. N. Wiley, *Treasurer;* Drs. C. H. Mann, J. D. Weaver, and J. O. Knipe, *Censors;* and Drs. D. H. Bergey, J. N. Hunsberger, and J. K. Weaver, *Examiners.* Delegates were also elected to the American Medical Association and the Medical Society of the State of Pennsylvania.

Spinal Meningitis in Horses.—It is reported that a fatal epidemic of spinal meningitis prevails among the horses in Phœnixville, Pa. When one animal is attacked the disease usually goes through the whole stable, and recovery is rare in those attacked. The veterinarians seem unable to check the inroads of the disease.

Philadelphia Medical Club.—At the annual meeting of the Philadelphia Medical Club, on January 13th, the following officers were elected for the ensuing year: *President,* Dr. John H. Musser; *First Vice-President,* Dr. Henry Beates; *Second Vice-President,* Dr. A. K. Minich; *Secretary,* Dr. Lemuel J. Deal; *Treasurer,* Dr. Wilson Buckby; *Board of Governors,* Drs. J. M. Barton, Frank Fisher, Charles K. Mills, A. H. Hulsizer, and W. E. Ashton; *Executive Committee,* Drs. J. H. W. Chestnut, L. Webster Fox, E. E. Montgomery, James Van Buskirk, and Guy Hinsdale.

Carrier Pigeons in Medical Practice.—Dr. Charles L. Lang, of Meridian, N. Y., writes: "I wish to call the attention of the medical profession, especially of the country doctors, to a means of messenger service that is at once inexpensive, effective, speedy,

and pleasant. I refer to the use of homing pigeons. For ten years past I have bred them and used them in my practice. When the condition of a patient is critical, especially if he lives at some little distance from the office, I can leave three or four birds with the nurse or some member of the family, who will release one at stated intervals, bearing a blank filled in with a detailed record of time, pulse, temperature, respiration, and remarks, etc., the whole enclosed in an aluminium capsule, made to clasp on to the leg (a recent invention), and away the bird speeds at the rate of from thirty to sixty miles an hour, in a beeline for his loft. When he enters the loft he passes through bolting wires that open inward into an enclosure about two feet square, where he is a prisoner till I remove his message, when he is turned loose with the other messenger boys to enjoy the society of his family till such time as he is needed again. Those who travel day after day over lonely country roads will appreciate any method of saving useless trips."

Scarlet Fever in East Orange is reported to have been spread by a milkman, who permitted his daughter, while convalescent, to cleanse the cans. It is said that twenty or thirty instances of the fever have occurred in families along his route.

New Treatment for Rabies.—Vapor baths combined with sudorifics is believed by Buisson, the discoverer of the method, and by others who have tried it, to be a cure for hydrophobia superior to that of Pasteur.

The War Against the Practising Physician.—There has been a disagreement among the officials of the Brownsville Dispensary in Brooklyn, and the seceding members of the dispensary staff have organized a new dispensary, under the name of the East New York Polytechnic Dispensary, and it has been opened in Osborn Street and Blake Avenue. It will be conducted on the basis of free medical attendance and ten-cent prescriptions, but the medicine will be furnished gratis to patients who are too poor to pay for it. And so the good work of pauperizing the poor and ruining the physicians goes merrily on.

Dr. J. F. Erdtman has been elected attending surgeon to the St. Mark's Hospital of this city.

Dr. L. Pierce Clark has been appointed first assistant physician at the Craig Colony for Epileptics, Sonyea, N. Y.

The International Language Question.—In the issue of the *Allegheny Literary Monthly* (Meadville, Pa.) for December, 1896, appeared an article, entitled "Modern Greek as the Universal Language," contributed by Dr. Franklin B. Stephenson, U.S.N.

Dr. Douglas Powell, physician extraordinary to the Queen and physician to the Middlesex Hospital, was created a baronet at New Year's.

The President of the Board of Health.—The New York Medico-Surgical Society has sent to the Greater New York commission a protest against the proposed clause in the charter providing that a non-medical member of the health board shall be president. The committee delegated to draw up the protest consisted of Drs. Fite, McEnroe, and Manges.

Pathological Society of Philadelphia.—A stated meeting of the Pathological Society of Philadelphia was held on the evening of January 14th in the lower hall of the College of Physicians. Dr. D. J. McCarthy exhibited a ruptured aneurism of the cœliac axis. Dr. D. Riesman exhibited specimens of miliary sarcomatosis of the liver and spleen, and also papilloma of the bladder causing death by hemorrhage. Dr. D. L. Edsall reported a unique case of occlusion of the œsophagus by tuberculous deposit, in conjunction with carcinomatous infiltration, and exhibited stained sections. Dr. Joseph McFarland demonstrated a heart presenting malignant endocarditis following gonorrhœa. Gonococci were not found in smear preparations, and, owing to the unfavorable condition of the subject, the results of bacteriologic culture could not be depended upon. Dr. McFarland exhibited also a specimen of verrucose endocarditis of the aortic valve. Dr. J. Dutton Steele read an interesting communication upon "The Distribution and Etiology of Cardiac Hydrothorax." From his studies he found that pleural effusions are commoner upon the right side than upon the left, and when bilateral greater upon the right than upon the left. The conclusion was reached that this distribution is dependent, in part at least, upon dilatation of the auricles, the right suffering the more commonly and in the greater degree. The effusion was attributed, among other influences, to this pressure exerted by the auricles upon the veins and the lymphatics at the root of the lungs, upon low grades of inflammation of the pleura, and upon changes in the blood-vessels and in the blood. Drs. J. H. Lloyd and J. D. Steele exhibited a specimen of hypertrophic cervical pachymeningitis. Dr. William G. Spiller exhibited a brain from a boy with extensive porencephaly in the speech centre, but who was at least able to sing. The left pyramid was wanting, although considerable motor power was preserved upon the right side of the body, but the right pyramid was considerably enlarged. It was pointed out that the functions of the destroyed or undeveloped parts of the brain had probably been taken up by the corresponding parts in the opposite hemisphere. Dr. J. D. Steele exhibited a perforating duodenal ulcer from a case of pneumothorax in a tuberculous subject.

Vital Statistics of Philadelphia.—For the week ending January 9th there occurred in the city of Philadelphia 513 deaths, of which 142 were of children under the age of five years. This number exceeded that of the preceding week by 11 and that of the corresponding week of the previous year by 24. The individual causes of the largest number of deaths were: pneumonia, 87; pulmonary tuberculosis, 64; heart disease, 31; diphtheria, 24; bronchitis, 23. There were reported to the board of health during the week 92 cases of diphtheria, 57 of scarlet fever, and 55 of typhoid fever.

Father L. L. Conrady, who succeeded Father Damien in charge of the leper colony at Molokai, Hawaii, has come to this country intending, it is said, to fit himself more thoroughly for his task by studying medicine. Another Father Damien, a brother of the dead priest, is in charge of the colony during Father Conrady's absence. The latter was interviewed by the reporter of a San Francisco paper concerning leprosy, and gave it as his opinion, formed from long observation of lepers in Hawaii and Japan, that leprosy can be transmitted only by inoculation. He believed that a person who takes proper precautions as to cleanliness and never allows any part of his skin that may be in any way abraded or broken to come into contact with the person of a leper may go on for years living among them without contracting the disease. Father Damien, he said, contracted the disease through his unwillingness to refuse attendance on a boy who had been badly hurt in an acccident. "Father Damien was suffering from a badly bruised hand, but, binding the wound with antiseptics and trusting for the best, he dressed the boy's wounds. His precautions were useless. He had become inoculated and it was not long before the marks of a leper appeared upon him." There are at present in the leper colony at Molokai 1,200 patients, 17 of whom are white men, 2 white women, 25 Chinese, and 1,156 native Hawaiians.

A Medical President.—M. Adolphe Deucher, who has just been elected president of the Swiss Confederation for the ensuing year by an almost unanimous vote, is, the *British Medical Journal* notes, a member of the medical profession. He was born in 1831, and was actively engaged in medical practice till 1879, when he retired in order to devote himself entirely to political life. He had, however, for some twelve years before that been a member of the Swiss Parliament, in which, though a stanch Catholic, he played a conspicuous part as a radical.

The Rinderpest Bacillus.—Professor Koch, who has been sent to South Africa at the expense of the British government to study the rinderpest, has a very easy job on his hands, if a Calcutta correspondent of the *British Medical Journal* is correct in his statements. He says that if the rinderpest in Africa is the same as that going under the name of rinderpest in India, then Professor Koch is going to search for a bacillus which Dr. Simpson, the well-known medical officer of health of Calcutta, has had in his possession for two and a half years. The organism is a sporeless motile bacillus which can grow both with and without air, but gradually becomes attenuated by repeated growths in air. Dr. Simpson saw Professor Koch in Berlin last May, and communicated to him the nature of his discovery. He was unable to show his cultures, having left them in London with Professor Klein a few weeks before.

West Branch (Pa.) Medical Association.—The sixth annual meeting of the West Branch Medical Association, embracing the counties of Lycoming, Union, Clinton, Northumberland, Bedford, Center, Clearfield, Huntingdon, Cameron, and Elk, was held at Bellefonte, Pa., on January 12th, and the following officers were elected for the ensuing year: *President*, Dr. J. Y. Dale, of Lemont; *First Vice-President*, Dr. George R. Nutt, of Williamsport; *Second Vice-President*, Dr. W. R. Palmer, of Johnsonburg; *Secretary*, Dr. J. M. Carson, of Chatham's Run; *Treasurer*, Dr. Mary Wensck, of Sunbury; *Executive Committee*, Drs. Hibler, Armstrong, McCormick, Stewart, Kane, and Henderson. A resolution was adopted for the appointment of a member of the society to present at the next meeting of the State society a paper praying for the appointment of a committee to inquire into the merits and demerits of cases of prosecution for malpractice and to assist the defence as far as possible. Among the papers read were the following: "The Treatment of Cancer of the Rectum," by Dr. W. W. Kenn, of Philadelphia; "A Case of Right-sided Pneumonia, with Pleuro-Pneumonia of the Left Side," by S. C. Stewart, of Phillipsburg; "The Treatment of Retrodisplacements of the Uterus," by Dr. B. F. Baer, of Philadelphia; "Some Clinical Facts," by Dr. H. G. McCormick, of Williamsport. The retiring president, Dr. R. B. Watson, delivered the annual address.

Berks County (Pa.) Medical Society.—The annual meeting of the Berks County Medical Society was held at Reading, Pa., on January 12th. Dr. M. A. Rhoads was elected *President* for the ensuing year, Dr. James W. Keiser *Secretary*, and Dr. Daniel Longaker *Treasurer*. Dr. Charles W. Bachman delivered the president's address, and the meeting was followed by a banquet.

Additional State Hospitals in Pennsylvania.—The Pennsylvania State board of public charities in its report to the legislature points out the "pressing need for an additional State hospital for the insane," "which should be permanently under homœopathic control and be solely and exclusively for the homœopathic treatment of the insane." The demand is also noted for an institution for the exclusive treatment of epileptics and the epileptic insane, to be called the "State Hospital for Epileptics of Pennsylvania," for which a bill has been prepared. A recommendation is made for legislation for the care, treatment, and detention in a separate State institution, of persons addicted to the habitual use of opium, morphine, cocaine, and the like and similar treatment for dipsomaniacs and inebriates. A proposition is endorsed to construct upon the grounds of the Western Penitentiary a building to be used as a State hospital for the convict insane.

University of Pennsylvania. —According to official statistics, the total enrolment for the current year in all of the departments of the University of Pennsylvania is 2,811—an increase of 179 over last year. The total number of teachers is 242, as compared with 251 last year. The medical department alone includes 920 students, an increase of 47; the auxiliary department of medicine 48, an increase of 4; the laboratory of hygiene 29, an increase of 6; the department of dentistry 373, an increase of 50; the department of veterinary medicine 50, an increase of

11. The medical department has 82 officers of instruction, the auxiliary department of medicine 5, the laboratory of hygiene 4, the department of dentistry 35, and the department of veterinary medicine 17.

In Aid of the Wounded Cubans.—The editor of the *Cleveland Medical Gazette* gives notice that he is ready to collect in Cleveland and vicinity whatever may be donated to the Cuban cause by physicians or pharmacists, in the line of medicines, drugs, and dressings, or money for purchase of the same, and to forward them to the proper Cuban agents to be sent to the front.

The International Medical Congress.—The titles and abstracts of all papers to be read at the Moscow congress should be sent to the executive committee not later than June 1, 1897.

The Fremont Polytechnic School.—Some colored men have been obtaining subscriptions in this city in aid of an institution with the above title, which they say is located in Alexandria, Va., and is for the education of colored boys. Inquiries addressed to the persons to whom the solicitors of funds refer bring the information that nothing is known of the alleged school.

"The Albany Medical Annals" appears with the new volume in a new dress and under the editorial management of Drs. Andrew MacFarlane and J. Montgomery Mosher.

"The Fort Wayne Medical Journal-Magazine" is the title of a new publication, formed by the consolidation of the *Fort Wayne Medical Magazine* and the *Journal of the Medical Sciences*.

Sir Joseph Lister, now Lord Kinnear, is not the first medical man to be raised to the peerage, but he is the first to be so honored for medical achievements. Lord Playfair, a qualified physician, was made a peer for political reasons solely.

To Prepare against the Plague.—The president of the Philadelphia board of health, Dr. William H. Ford, has been appointed a committee of one to confer with the secretary of the State board of health and the quarantine physician on the subject of the bubonic plague, with a view to preventing its possible entrance into the port of Philadelphia.

The Founder of the Red Cross Society, M. Henri Durant, is in an almost penniless condition. A committee, therefore, has been started in Stuttgart, in order to raise a sufficient sum of money for the purpose of providing for him in his old age. Contributions may be forwarded to the "Henri Durant Fund," care of the burgomaster, Stuttgart.

A Victim of the Dispensaries and Their Rival.—A pitiful tale is told in the London *Daily Telegraph*, of the straits to which the humbler members of the medical profession in that metropolis are reduced by the multiplication of dispensaries and the growing evil of club practice. Among other instances it is related that "one fully qualified medical man, who is said to have passed his examinations with brilliancy, has descended to a lower depth than even the sixpenny doctor. He is settled in one of the poorest districts of St. George's-in-the-East, and outside his surgery is painted in bold Roman letters: 'Advice and Medicine, 4½*d*. Superior ditto, 6*d*.' Where the three-halfpennyworth of superiority lies is a puzzle to the more thoughtful inhabitants of the district." Commenting upon this case, the *Medical Times* says that "when a leading London daily paper draws attention to conduct of this kind on the part of members of an honorable profession, it affords convincing evidence of the degradation to which many of our poorer brethren have been reduced. It is not reasonable to suppose they can choose such work, and it can only be presumed it is the *res angusta domi* that forces them thus to drag in the dirt their professional dignity." The causes for this "degradation" enumerated by our contemporary are the old familiar ones of competition with lodge doctors, unqualified practitioners, dispensaries, and patent-medicine makers.

Ball for Medical Charities.—The seventeenth annual Charity Ball was held in the Academy of Music at Philadelphia, on January 21, 1897, and was eminently successful. The proceeds will be equally divided among the Maternity Hospital, Howard Hospital, the Polyclinic Hospital, the Gynecean Hospital, the Philadelphia Lying-in Charity and Nurse School, and the Rush Hospital for Consumptives.

"The Edinburgh Medical Journal" appears with the new year in a new dress, under new editorial management, and with a new publisher. The editor is Dr. George A. Gibson; the publisher, Young J. Pentland. The contents of the journal are of the high order characteristic of this excellent publication.

The Meeting of the British Medical Association.—The city council of Montreal has asked the Quebec legislature for permission to appropriate $3,000 to help defray the expenses of the meeting of the British Medical Association in that city in August next.

Dental Department of the Medico-Chirurgical College.—The matriculation books of the new dental department of the Medico-Chirurgical College of Philadelphia were opened on January 25th for the registration of students. The course of instruction will begin next October, and will cover a period of three years. The professors of anatomy, physiology, and chemistry will be the same as those in the medical department of the college.

Franklin County (Pa.) Medical Society.—The quarterly meeting of the Franklin County Medical Society was held at Chambersburg, Pa., on January 19th. Delegates were elected to the American Medical Association and to the Medical Society of the State of Pennsylvania.

Dr. G. Sims Woodhead, director of the research laboratory of the conjoint board of the Royal Colleges of Physicians and Surgeons, has been elected president of the British Medical Temperance Association, in place of the late Sir Benjamin Ward Richardson.

Society Reports.

MEDICAL SOCIETY OF THE STATE OF NEW YORK.

Ninety-First Annual Meeting, Held at Albany, January 26, 27, and 28, 1897.

JAMES D. SPENCER, M.D., OF WATERTOWN, PRESIDENT.

Tuesday, January 26th.

President's Inaugural Address.—DR. SPENCER, of Watertown, read a brief inaugural address. It was a matter for congratulation that we had the most active State medical organization in the United States. In obtaining medical legislation in certain important directions the society had been ably seconded by the homœopathic and eclectic State societies. The loss by death included a number of well-known members. The State board of health should be given absolute control of the water supplies of the State, with a view to prevention of their contamination. A larger appropriation should be made for carrying out the law for the destruction of tuberculous cattle. Offensive trades should be more thoroughly under the control of the health board. It was recommended that a committee of five or ten be appointed to meet committees from other State societies and consider the question of establishing a national confederation of committees of legislation of State medical societies. There had been an increase in the number of medical and law students in the State in spite of the lengthened term. The proportion of medical students in New York State was seventeen per cent. of the whole number in the United States. Before the State board of medical examiners 733 candidates had taken the examination; 552 were successful, 181 unsuccessful. Before the homœopathic board 52 were examined; 40 of them were successful. Before the eclectic board, 20; 18 of them were successful.

Report of State Board of Medical Examiners.—DR. MORRIS J. LEWI read the report. The number of candidates was essentially as stated above. Since the establishment of the board the students in the State had increased instead of decreased. The property of the medical colleges had increased over one hundred per cent. The State board of Pennsylvania no longer recognized a license from the New York State board, because the latter did not recognize a license from it. But the standard was too low in Pennsylvania to permit the New York board accepting a license granted in that State. Since the board had been established there had been 2,832 applicants, of whom 927 had been rejected, or 29.2 per cent.

Report of Legislative Committee.—DR. A. WALTER SUITER read the report. Its work had been to oppose certain bills and introduce others. The bills which were favored or opposed related to exemption of certain persons from taking the State examination, to vivisection, alcoholic education, midwifery license, optic society bill, chiropodist bill, reorganization of coroners. The report was adopted.

Report of Treasurer.—DR. PORTER, of Albany, reported as expenditures, $5,349; balance, $2,778.

DR. F. C. CURTIS read the report of the committee on publication, which was approved.

Report of Committee on Legislation.—DR. HOPKINS, of Buffalo, read the report. Nine-tenths of the deaths in the State were unnecessary, and must be taken as a measure of our inefficiency. The principles and practical rules of hygiene must be discovered and initiated and public opinion must be created to appreciate such principles and support such action. The committee thought the society should advise the formation of local societies in which doctors and the public should inform themselves on matters of hygiene, particularly in connection with their own towns. They might report to the State society through its committee on hygiene. A motion was adopted recommending that steps be taken to organize local sanitary societies, as suggested in the report.

Committee on Vivisection.—DR. W. O. STILLMAN, of Albany, moved that a committee of three be appointed in compliance with a request from the Humane Society to confer with a similar committee from that society to consider legislation bearing on vivisection. The motion was adopted, and Drs. A. Jacobi and Albert Vander Veer were appointed as two of the committee.

Irregular Practitioners.—DR. WILDY called attention to the fact that there was a maximum punishment of $250 for irregular practitioners, but no minimum punishment was named. The consequence was usually an insufficient fine, especially by country justices. The matter was referred to the committee on legislation for consideration.

Length of College Course.—DR. DANIEL LEWIS moved that in view of the long course now required of students in medicine, the committee on legislation be directed to draft a bill to modify the present law and allow medical students, graduates of literary colleges, to be credited with the last year of study in such literary college. The motion was seconded by Dr. Roosa, who said that under the law, if not changed, one would not be ready to practise medicine before his thirtieth year. The requirements and duration of studies exceeded those in Germany. The resolution was adopted.

A Geographic and Arithmetic Lesson on Blindness in New York.—DR. LUCIEN HOWE, of Buffalo, read the paper. Twenty-one per cent. of all the blind in the asylums of this State had become so from ophthalmia neonatorum. There was an efficient preventive, the Credé method, or instillation of a solution of nitrate of silver into the eyes of the newly born. He favored a law requiring its use in all institutions, if not as well in private practice.

DRS. MOREL, BENDELL, and VAN FLEET approved of the Credé method, but did not believe it ought to be made obligatory upon the medical profession.

The Fitting of Glasses.—DR. M. L. FOSTER, of New York, read the paper. The author and those who discussed the paper, DRS. ROOSA and VAN FLEET, claimed that every graduate in medicine nowadays had sufficient knowledge of ophthalmology to fit glasses in most cases and decide whether any operation was necessary to correct reflex epilepsy, etc. But a knowledge of general medicine was essential, and they opposed the prescribing of glasses by opticians.

A Contribution to the Study of Cough Due to Irritation of the Upper Respiratory Tract.—DR. CHARLES N. COX, of Brooklyn, was the author of this paper. In his experience the most frequent sources of nasal cough were disease in (1) posterior part of inferior turbinated, posterior end of septum; (2) similar part of middle turbinated and of septum opposite. Another source of cough was in the pharynx. The author thought a good many cases of cough were caused by conditions above the larynx, although they were scarcely mentioned in text-books.

DR. JOHN O. ROE had found a number of cases of cough due to enlargement or disease of glands at the base of the tongue.

Practical Conclusions Drawn from a Study of Five Hundred Cases of Cardiac Disease.—DR. JAMES K. CROOK, of New York, read a paper giving practical conclusions drawn from a study of five hundred cases

of cardiac disease, with special reference to the comparative prognosis of the valvular lesions. Out of 6,000 patients examined at the hospital in a given period there had been 500 of disease, functional or organic, of the heart or vessels; 277 were functional, 226 were organic. The organic were subdivided into: mitral regurgitant, 60: mitral stenosis, 35; aortic regurgitant, 7; aortic stenosis, 36; tricuspid regurgitant, 36; pulmonic stenosis, 1; double aortic lesions, 19; double mitral, 12; aortic stenosis and mitral regurgitant, 4; also a few other combinations of lesions. There were more cases of organic lesion in males, more of functional cases in females. Aortic disease was more common in males, 51 cases to 29 in females. While mitral regurgitant was the most frequent of all valvular lesions, it was the most hopeful. They had kept many patients under observation many years, in whom there was no particular discomfort. In aortic inefficiency water-hammer pulse was as valuable a physical sign as murmur.

Dr. Richard Van Santvoord, of New York, called attention to the value of the sphygmograph in determining the amount of regurgitation. Hammer pulse might be due in some degree to want of elasticity in the arteries; but it was an unfavorable sign, whether due to this cause or to aortic inefficiency.

Dr. Long continued the discussion.

Some Diseases of the Alimentary Canal in the Light of Its Development and Ancestry.—Dr. Woods Hutchinson, of Buffalo, had time to read a part of a paper on this subject, and to make demonstrations. The development of the digestive tract was traced through amœba, hydra, anemone, molluse, worm, fish, sheep, dog, man. In the bearing of development upon diseases of the stomach, attention was called to the sacculations and distention of the organ, seen hardly ever in dogs, but frequently in the horse and ox, and more often in man than many believed.

Some Unusual Causes of Cough.—Dr. Emil Mayer, of New York, in this paper mentioned cases of disease in the naso-pharynx and pharynx as causes of reflex cough, among them one case of leptothrix pharyngeus. Signs of a reflex cough were spasmodic paroxysms without expectoration or rise of temperature; further, when there was absence of physical signs of pulmonary and bronchial disease; further, when there was persistent resistance of medication; also when the general health remained comparatively undisturbed.

Does the United States Pharmacopœia Keep Pace?—Dr. Eli H. Long, of Buffalo, in this paper referred to the initiation of the United States Pharmacopœia by this society in 1818. In its first revisions, 1840, 1850, there were more delegates from the medical profession than from the pharmaceutical. But the pharmacists had steadily increased since 1860 to 1890. He thought this society should take a more active part. There were two questions of interest, namely, (1) whether to introduce dosage; (2) whether to introduce certain synthetic preparations which might be proprietary. For some years almost our sole information regarding new remedies had come from the pharmaceutical chemists.

Dr. L. F. Bishop spoke of the deception of some manufacturers in passing as synthetic agents a combination of agents, especially some of the coal-tar series with bicarbonate of sodium, etc.

The Effects of Cigarette Smoking on the Respiratory Mucous Membrane.—Dr. C. C. Rice, of New York, in this paper referred briefly to the literature bearing upon the poisonous agents in cigarettes, the extent of their use, their greater use by the youth than cigars, their effect upon the nerves, etc. Dr. Rice thought it was sufficient to recognize nicotine as the poisonous agent, in condemning the use of cigarettes, although other injurious agents might also be present. It had been estimated that fifty cigarettes for every inhabitant were sold in this country. During the last few months the reader had seen five cases in young men addicted to excessive cigarette smoking of atrophic catarrh and congestion of the larynx and trachea, causing cough. The atrophic rhinitis was not of family type, and as it occurred in all five cases with the same symptoms he attributed it to the cigarette habit. In this habit the tobacco smoke penetrated nose and trachea usually, and it was to be expected it would cause irritation and drying up of the secretions. Dr. Rice approved of legislation against cigarette smoking.

Dr. Emil Mayer agreed as to the injurious effects of smoking, but questioned the advisability of restrictive legislation.

A Contribution to the Study of Amœbic Dysentery.—Dr. Charles E. Lockwood, of New York, read the paper and related a case of amœbic dysentery, in which for some time the cause of the dysentery was not recognized. Finally, repeated microscopic examinations of the stools revealed the amœba. The treatment was chiefly by rectal irrigation with solution of quinine, increasing in strength from 1 to 3,000 to 1 to 1,500, resulting in a cure in five days. The diagnosis should be made early if possible, that treatment might reach the amœbæ before they penetrated the submucous tissue, got beyond the reach of the medicinal agent, and finally caused abscesses in neighboring or somewhat distant organs.

Fancies and Facts in Our Work.—Dr. Joseph Eastman, of Indianapolis, in this paper took opportunity to express views on treatment of cancer of the uterus and some other pelvic diseases, on drainage (which he believed in under some circumstances), on sterilization, on appendicitis, etc. He did not believe in the French innovation of doing all hysterectomies by vagina. Regarding appendicitis and intestinal obstruction, the course of treatment should be early decided, whether medicinal or surgical, and the fatal compromise of operating only because medicinal treatment failed should be avoided.

Dr. Fowler, of Brooklyn, spoke of inversion of the appendix into the cæcum as extremely dangerous, and mentioned a fatal case. It should never be done.

Dr. Eastman did inversion of the appendix, which Dr. Fowler condemned, but would remember the danger and be more cautious. One should be cautious not to strangulate the circulation.

The Correction of Depressed and Saddleback Deformities of the Nose by Operations Performed Subcutaneously, without the Aid of Artificial Supports.—Dr. John O. Roe, of Rochester, read the paper. The deformities in question were natural or traumatic, and the presence of the bony support made it unnecessary to use a metallic or artificial one. When the bones were broken or destroyed by disease, the artificial support must be supplied. The operation varied with the case, but was always subcutaneous, the soft tissues of the nose when excessive being transplanted into the defective portion. Thus Dr. Roe had corrected pug nose, had lifted up the depressed end of the nose, etc. Extreme care in asepsis and antisepsis was required, and also in the after-treatment.

Dr. Mayer thought much credit was due to Dr. Roe for his original work and writings on correction of nasal deformities.

Gauze Drainage in Surgical Gynecology.—Dr. Willis E. Ford, of Utica, read the paper. He thought there was more danger of iodoform poisoning from iodoform gauze than some believed. The author used gauze drainage, sometimes with boric acid, sometimes with acetanilid solution.

Drs. Eastman, H. J. Collyer, A. P. Dudley, and W. B. Chase discussed the paper.

Absorbable Ligatures and Sutures in Pelvic and Abdominal Surgery.—Dr. Walter B. Chase, of Brooklyn, read the paper. He found catgut answered the conditions required when chromicized—those of sterility, pliability, strength, and endurance. It would last even as long as forty days.

Obstetrical Discussion.—Dr. W. W. Potter, of Buffalo, had arranged a discussion on obstetrics, and read the introductory paper on

Puerperal Eclampsia.—The microbic theory, Dr. Potter said, had not yet been demonstrated; the toxæmic theory offered the best working hypothesis. Treatment was preventive and curative. The preventive was medicinal and hygienic; the curative was medicinal and obstetric. Active convulsions should be controlled by chloroform. If convulsions were not thus promptly stopped, the uterus should be emptied. Rarely were deep incisions necessary. Cæsarean section should be done only in deformities or when the mother's condition was hopeless. Veratrum viride was dangerous and deceptive in action. Induction of labor and stimulation of excretions received consideration.

Indications for and Technique of the Induction of Premature Labor.—Dr. James P. Boyd, of Albany, read the paper. The indications were several; the method he preferred was the introduction of a solid flexible bougie into the uterus. Every step must be strictly aseptic.

Infection of the Puerpera.—Dr. A. B. Miller, of Syracuse, was the author. Puerperal fever was due to infection: usually the septic material was introduced through the parturient tract, especially at the cervix. The importance of aseptic technique in obstetrics and in treatment was dwelt upon. Attention should be directed to the cause rather than to the symptoms.

Obstetric Delivery by Abdominal Section: Indications and Method.—Dr. Willis G. Macdonald, of Albany, read this paper. Craniotomy on the living child was wholly out of place. It was more dangerous than hospital statistics would indicate. Symphyseotomy in the general practitioner's hands was also likely to give much less favorable results than statistics up to the present, contributed by experts, would indicate. The Porro operation, except in a few cases, was the proper one.

Present Treatment of Fibroids Associated with Pregnancy.—Dr. Albert Vander Veer, of Albany, was the author. Experience taught us that subperitoneal fibroids located in the upper portion of the uterus might remain without injury to mother or child, and perhaps disappear after pregnancy. Submucous fibroids sometimes became polypi and were removed without difficulty. In fibroids of long standing complicating pregnancy, Dr. Vander Veer advocated the Porro operation.

Dr. W. M. Polk opened the general discussion. For fibroids of the character referred to by Dr. Vander Veer, he recommended the Porro operation. In eclampsia with rigidity of cervix which could not be overcome, he made incisions, and preferred anterior to lateral or posterior incisions.

Drs. H. J. Boldt, Von Ramdohr, A. P. Dudley, Sears, and the readers of the papers continued the discussion.

Observations on Abdominal and Pelvic Surgery; Preparation, Operation, and Results.—Dr. W. Gill Wylie, of New York, read the paper which will appear in a future issue.

Causes of Death Following Abdominal Operations.—Dr. H. J. Boldt, in this paper, attributed most deaths in abdominal operations to peritonitis. This was the cause in many instances in which it may hardly have been suspected. Reduction of vitality by recent pneumonia, etc., probably favored the development of germs causing peritonitis, and therefore after acute diseases he postponed abdominal operations if possible. Dr. Boldt cautioned against the use of the Murphy button in anastomosis of the large intestine. Narcosis should be in the hands only of experienced men, and he favored a law to this effect.

The evening session on Tuesday was held in the new Bender laboratory, and was devoted to lantern exhibitions, first by Dr. R. H. Sayre, illustrating "Posture in Diagnosis of (Orthopædic) Disease;" second, "X-Ray Stereopticon Exhibition," by Dr. W. J. Morton, who also took an *x*-ray photograph of a fractured leg and showed other photographs. Dr. Hailes also exhibited photographs in three cases of fracture, and spoke of the value of the method in diagnosis.

The Bender laboratory is situated many blocks distant from the capitol and present college buildings, but in the course of time the medical college and hospitals will be on the ground about the laboratory.

Wednesday, January 27th.

Medical Examiners.—The committee to recommend candidates for medical examiners, three vacancies, reported the names of Drs. W. W. Potter, M. J. Lewi, W. S. Ely, A. W. Suiter, Daniel Lewis, R. W. Stoddard. The report was adopted.

Deficient Excretion from Kidneys not Originally Diseased, as Related to Some Diseases Peculiar to Women and Diseases of the Skin.—Dr. L. D. Bulkley, of New York, took for the title of his paper that of the address of Dr. Etheridge, read before the society last year, and stated that the importance of the subject led him again to call attention to it. Last year he alone discussed it, in connection with diseases of the skin. He had observed that in many cases of disease of the skin there was deficient elimination of urinary solids and that the urine was deficient in quantity, and on correcting these the skin affection was not alone improved or cured, but uterine compaints also disappeared.

Drs. Hopkins, Wilcox, Hutchinson, Bristow, and Walker generally agreed with Dr. Bulkley as to the importance of estimating the daily amount of urine and solids and the value of increasing elimination in the treatment of skin and other affections.

Too Many Papers.—Dr. L. D. Bulkley offered a resolution to limit the number of papers to be presented to the society to fifty as a maximum. This was to give more time for reading papers and for discussion.

The resolution was referred to the committee on bylaws.

Dr. Hun reported against awarding a prize this year.

Committee on Pharmacopœia.—Dr. Long moved to appoint a committee of three on revision of the pharmacopœia. Carried.

Sale of Alcoholics by Druggists.—Dr. Long offered a resolution, adopted by the State Pharmaceutical Society, asking the legislature to relax the law for the sale of alcoholics for medicinal purposes by druggists. It was referred to the committee on legislation, with power.

Dr. W. C. Wey's Illness.—A resolution of sympathy with Dr. Wey in his illness was adopted.

The Treatment of Heart Disease.—Dr. Thomas E. Satterthwaite, of New York, read the paper. It was his intention to speak of some modern methods of treating heart affection when there was inefficiency. The precise nature of the lesion was of subordinate importance. In diet he agreed with Grainger Stewart, that nitrogenous food should be increased, the hydrocarbons reduced and liberal potations of fluid given in

lithæmia and uric-acid secretion. It was not always safe to cut off alcohol abruptly; the daily amount should be reduced slowly. Next in importance was regulated exercise. This included chiefly modern systematic resistance movements associated with the name of Schott. Having briefly described such exercises, the speaker said the next point in treatment was baths—warm salt water which had been carbonated. The effects of these baths, in his opinion, were much like that of the exercises, but they were less efficient. Finally, Dr. Satterthwaite briefly reviewed medicinal remedies—digitalis, strophanthus, caffeine, nitroglycerin, etc. Arsenic and iron were valuable aids in many cases. Dr. Satterthwaite had treated seven cases by graduated exercises, with or without baths, all with improvement.

Dr. R. W. Wilcox thought Dr. Satterthwaite had presented the Schott and Bad Nauheim treatment impartially, and characterized some of the reports of English observers as absurdly exaggerating the value of such treatment.

Dr. Elsner spoke against the blind use or abuse of nitroglycerin and nitrite of amyl. They did harm in a state of soft dilatation of the vessels.

Dr. Russell spoke of harm from abuse of digitalis.

Practical Points Relating to the Diagnosis and Management of Syphilitic Brain Disease.—Dr. E. C. Spitzka, of New York, gave an outline of his paper. The general practitioner and even the specialist were liable to mistake syphilis of the brain, especially in its early stage, for melancholia. In melancholia there were true depression, suicidal tendency, insomnia; in syphilis of the brain the depression was variable, was apparently related to business trouble, the suicidal threat was seldom carried out, there was no insomnia, but there were hebetude and sleepiness. Another mistaken diagnosis was of neurasthenia, a convenient term to cover ignorance. Mention was also made of pupillary reflexes, of pneumogastric disturbances related to the stomach, etc. The importance of an early diagnosis was apparent by mention of monoplegia, apoplectiform attacks, dementia, which would result from syphilis if prompt and vigorous treatment were not resorted to. This consisted in the use of mercury and iodide of potassium.

Dr. F. R. Sturgis expressed greatest reliance on iodide of potassium in huge doses.

Dr. Bulkley placed more stress on mercurials.

Dr. Williams spoke of the value of subnormal temperature in diagnosticating syphilis of the brain.

Drs. Sherman and Hopkins also spoke.

The Treatment of Locomotor Ataxia.—Dr. Landon Carter Gray, of New York, was the author. In pathology the Charcot school had for years been dominant, and the system theory, referring lesions to tracts in the cord, was the one which had been largely accepted in relation to locomotor ataxia. This view of the pathology had led to rather a hopeless view in treatment. But lately some diseases which might have been regarded as incurable on the supposition that they belonged to the systemic class had been in some instances regarded as at least starting in the posterior ganglion cells or even in the peripheral nerves. Our knowledge of the pathology of locomotor ataxia and some of the other diseases referred to was not so complete as to justify a necessarily hopeless prognosis, although to prove absolute cure in cases of disappearance of the clinical symptoms was impossible in the absence of autopsy. Dr. Gray had seen almost startling improvement in some cases of locomotor ataxia under the treatment described. In all he had treated about seventy-seven cases, and could speak of the result as satisfactory, without claiming that the disease was eradicated. In order of importance the measures were: 1, Rest; 2, nutrition; 3, removal of reflex disturbances; 4, drugs directed against the lesion. Rest was governed by the stage of the disease and the result, sometimes being absolute for days or weeks, and always for ten or twelve hours a day at least, including hours of sleep. Regarding drugs, he was not one of those who believed that syphilis was always the cause of locomotor ataxia, yet in some cases antisyphilitic treatment was followed by striking improvement. Whenever there was a history of syphilis, such treatment should have a thorough trial.

A Case of Erythro-Melalgia.—Dr. Henry L. Elsner, of Syracuse, read the history of the case. It was in a washwoman, and began with headaches in 1893, also flushing of the face. Later there were burning sensations in the palms of the hands, then soon a maculo-papular erythema of the hands. With this the headaches disappeared. The painful sensations in the hands were extreme. Gradually dark discoloration appeared in the thumbs, terminating in some months in dry gangrene and falling off of the terminal phalanx of each thumb. Then the erythema and pain disappeared and the hands were well, with the loss of the two phalanges. This case was the forty-fourth of erythro-melalgia on record. The pathological explanation was regarded as long-continued hyperdistention of the vessels in the erythematous condition, resulting in final cutting off of the circulation and dry gangrene.

Strophanthus: a Clinical Study.—Dr. R. W. Wilcox, of New York, was the author. There were four distinct varieties of strophanthus. The value of all of these had not been determined clinically. Dr. Wilcox had studied Strophanthus Kombé clinically in numerous cases since 1885, and had taken a great many sphygmographic tracings. His conclusions were that this form of strophanthus increased the action of the heart by direct action on the heart muscle; it acted with a degree of rapidity not equalled by any other cardiac tonic; it had no effect on the size of the blood-vessels; it had an eliminative effect; it was not cumulative in action; it was far more powerful than digitalin, three hundred times by weight.

Discussion on the Relation of Impure Drinking-Water to Disease.—Several papers bearing on different phases of this question were read.

Diseases which can be Directly Traced to Contaminated Drinking-Water.—Dr. George Blumer, of Albany, read the first paper. There was certain proof that we may have cholera, typhoid, certain diarrhœas, and some forms of mineral poisoning carried by drinking-water. The conclusion was evident that without pure drinking-water we could not have a healthy community.

Dangers of Domestic Use, Other than Drinking, of Contaminated Water.—Dr. G. R. Freeman, of New York, was the author. The greatest danger was from milk contaminated by washing of cans in impure water, dilution, etc. Further, foods might be rendered dangerous, and he mentioned oysters as having been infected, and, probably, other shellfish. The germs most frequently carried by water not drinking-water were those of typhoid, cholera, and diphtheria.

Methods of Purification of Impure Water.—Dr. T. B. Carpenter, of Buffalo, gave an analytic study of methods of water purification practised in this country and Europe. The methods were the so-called natural and artificial. The latter was mechanical and chemical. The chemical included the use of electricity. The filtration method received considerable attention. In this country filtration through sand, etc., was used in Davenport, Knoxville, Atlanta, Chattanooga, and some other places. The diminished number of germs in the filtered water pointed to a certain and large value of the method.

Methods of Prevention of Pollution of Water.—Dr. E. K. Dunham, of New York, discussed this

question. The best method was putrefaction, exposure of the sewage near the surface of the soil accessible to the air, where the germs producing putrefaction could act and destroy the disease germs—a process described as mineralization.

Life History of the Typhoid Bacillus Outside of the Body.—Dr. F. C. Curtis, of Albany, read the paper. Under favorable conditions the typhoid bacillus retained its vitality a long time outside the body. It withstood cold, was destroyed by heat, was very susceptible to the attack of other germs, and was destroyed under other conditions.

The author dwelt most on the life history of the typhoid bacillus in the soil. In this connection the fact frequently observed was mentioned, of typhoid visiting simultaneously villages in a section separated by some distance, with different water supplies and no intercommunication.

Such occurrences pointed to deposit of the typhoid bacillus in the soil; its vitality was retained and the bacillus was carried into the drinking-water with the fall of rain. Aerial contamination could be practically excluded.

Bacteriological Diagnosis of Typhoid Fever.—Dr. J. S. Ely, of New York, said the bases of a bacteriological diagnosis were: (1) finding of the specific bacteria; (2) of their products; (3) of the specific toxins liberated by them in the body; (4) of certain substances liberated in the blood of the patient in the course of its reaction to the bacteria. The author pointed out difficulties connected with the first three methods. Time did not permit of reading more of the paper.

Typhoid Fever in Children.—Dr. W. P. Northrup, of New York, stated in this paper that during the fourteen years he had been connected with the New York Foundling Asylum he had not seen a case of typhoid in infants during the first two years of life, and Drs. Smith and O'Dwyer had seen none in a longer period in the same institution. In no autopsies had he found typhoid lesions in such subjects. Dr. Holt had seen none at the Infant Asylum, which had over seven thousand inmates. While infants were not easily infected, yet he had seen four such cases in the Stamford epidemic out of over four hundred cases of typhoid.

Importance and Practical Method of Disinfection of Excreta of Typhoid Patients.—Dr. W. Gilman Thompson, of New York, read an outline of his paper. Bichloride solution was strong and cheaper than most other disinfectants, but was not applicable in city closets; there carbolic acid, 1 to 10, was used. Tidewater rendered the typhoid sewage harmless. In the country, bichloride from 1:500 to 1:2,000 should be used in vessels, etc. The disinfected fæces should be buried four feet deep. Disinfection of hands, of nurse, of door-knobs, etc., should be insisted on. The clothing should be boiled after disinfection. The perineum and anus of patients should be disinfected after each passage. The urine should be disinfected like fæces. Quicklime and formalin were mentioned.

Prof. W. T. Sedgwick, of Massachussetts, in discussing the paper, said mechanical purification had rendered the water of the town of Lawrence as free from typhoid germs as that of other cities, whereas previously the death rate from typhoid there had been considerable.

Double Murphy Button Anastomosis.—Dr. J. H. Glass, of Utica, related a case of intestinal obstruction from sarcoma of the colon. Seven inches of colon and four inches of ileum were removed, and anastomosis with double Murphy button was performed, the largest button for the colon, the next in size in the ileum. The latter passed last, after twenty-six days, and probably was meanwhile the cause of colic. The patient was doing well nine months after operation.

Some Clinical Cases of Diseases of the Testicle.—Dr. L. B. Bangs read the histories of five cases bearing on difficulties of diagnosis and treatment. In one, of hard painful tumor in an aged man, in which there was reason to suspect malignant disease, the tumor proved to be benign, with pus between the testicle and dense tunica. In the case of a young man the tumor was soft, not painful; there was reason to believe it was benign, but it proved to be malignant.

Drs. Sturgis and B. F. Curtis discussed the paper.

A Rare Complication of Acute Rheumatism.—Dr. Eugene Beach read the history of a man who, after sleeping in a damp bed, had painful swelling of the testicle; a few days later there was pain in the outer side of both thighs (the subject thought it to be sciatica); after two weeks a mild cystitis; then a slight urethritis, with exacerbation of inflammation in the testicle. This gave place in five days to acute articular rheumatism, which continued three weeks, and subacute swelling longer. Dr. Beach thought the case belonged among the rare ones of acute rheumatism among whose first or later manifestations were orchitis, cystitis, and urethritis.

Notes of Cases of Suggestive Therapeutics (Hypnotism).—Dr. H. S. Drayton, of New York, thought hypnotism, or suggestive therapeutics, was one of those remedial agents whose value this country had been much slower to recognize than it should. In Europe many hospitals were devoted to its application. Among cases which he briefly narrated was one of epilepsy of years' duration; over four hundred dollars' worth of ordinary remedies had been taken. Hypnotic suggestion as to the diet, etc., stopped the attacks and caused remarkable general improvement, as well as improvement in mind.

Dr. W. J. Morton had seen much of hypnotism and had employed it, but believed that in all but exceptional cases it did harm by taking away from the will power or moral power of the individual.

Rectal Discussion.—Dr. Joseph M. Matthews, of Louisville, Ky., opened this discussion with a paper on

Stricture of the Rectum; Its Etiology and Treatment.—Dr. Matthews expressed regrets at the absence of Dr. Kelsey, as his paper was an answer to criticisms by that writer on one of his papers. Dr. Matthews regarded syphilis as the cause in about sixty per cent. of the cases.

Surgical Treatment of Cancer of the Rectum.—Dr. Daniel Lewis was the author. Three facts were to be considered before resorting to operation: (1) the general condition of the patient; (2) had the disease been of rapid or slow growth; (3) choice of operation for complete removal. To indicate operation the disease should be, say, not more than four inches from the anus, with vagina, bladder, and peritoneum free and no glandular enlargements. He preferred the modified old Volkmann operation to Kraske's or others. In women he would operate per vaginam.

Proper Method of Treating Internal Hemorrhoids.—Dr. R. T. Morris, in the first part of his paper, considered the anatomical and pathological problems involved in the question of hemorrhoids and their treatment, and characterized ointments and other medicinal applications as only palliative. He had only reached the operative treatment when his ten minutes had expired.

Prolapsus of the Rectum.—Dr. George R. Fowler read a paper on this subject, and Drs. B. F. Curtis and J. P. Tuttle took part in the general discussion.

Acute Inflammation of the Gall Bladder.—Dr. Maurice H. Richardson, of Boston, in this paper gave the histories of six cases of acute inflammation of the gall bladder operated upon. In a number, the diagnosis between this affection and appendicitis was determined only at operation. These symptoms

were much alike in the two affections, and the location of the pain might not be diagnostic. In case of doubt he recommended midway incision, to be extended up or down, according to whether appendicitis or inflammation of the gall bladder were found. In acute inflammation of the gall bladder there was usually absence of duodenitis, of attacks of biliary colic; stones were present, however, and also micrococci in the distended bladder, which might be colon bacilli, typhoid bacilli, diplococci of pneumonia, etc. Operation was necessary.

Discussion by Drs. Vander Veer, Fowler, Macdonald, and Howard.

The President's Annual Address.—The President, Dr. James D. Spencer, chose for the subject of his address the country practitioner. The country doctor might theorize, but he must be practical. He must stand absolutely on his own merits. There was no hospital with its trained nurses to assist him, and no daily papers to herald his successes. It was better to study carefully and handle in a masterly manner a single case than to try to throw a cloud of doubt on many. We were traitors to our patients, to ourselves, and to society at large if we neglected to keep the most efficient ammunition that science provided for us. But the arduous life of the country doctor had its compensations. All knew how pain and fear vanished in the presence of the physician. The most intimate secrets were confided to his keeping. Wounds, not only of the body, but of the soul, were laid bare before him. The country doctor needed to be a man of many parts—a drudge, a hero, a martyr of time for the cause he represented.

On motion of Dr. Bendell, the president was extended a vote of thanks for his interesting and instructive address.

Thursday—January 28th.

Officers.—*President*, Seneca D. Powell, of New York; *Vice-President*, Lucien Howe, of Buffalo; *Secretary*, F. C. Curtis, of Albany; *Treasurer*, C. H. Porter, of Albany; *Committee of Arrangement*, W. J. Nelis, William Hailes, R. W. Wilcox; *Committee on By-laws*, H. D. Wey, E. B. Angell, F. C. Curtis; *Committee on Hygiene*, H. R. Hopkins, H. F. Hart, C. E. Bruce, A. Vander Veer, William Maddren, O. W. Peck, Ernest Wende; *Committee on Legislation*, A. W. Suiter, E. M. Morrell, W. G. Macdonald; *Committee on Ethics*, J. M. Winfield, Eugene Beach, Louis A. Weigel; *Committee on Prize Essays*, E. D. Fisher, Henry Hun, W. S. Cheeseman; *Committee on Publication*, F. C. Curtis, Daniel Lewis, W. W. Potter, C. H. Porter.

Surgical Suggestions.

Subpleural Pulmonary Abscess.—1. Closed pulmonary abscesses are abscesses of the connective tissue, of which the most favorable and the most common form is the subpleural abscess. 2. The subpleural abscess may attain a large size without causing a corresponding destruction of pulmonary tissue; for the individual pulmonary lobules, isolated by the suppurative process, retract before the pus in a manner analogous to the retraction of the lung as a whole in the presence of pleural effusion. 3. The frequency of the occurrence of subpleural abscess is probably greater than is commonly supposed; for this abscess simulates empyema so closely that it is generally mistaken for that disease. 4. The only trustworthy means of distinction between these two diseases is probably the microscopic examination of pus withdrawn by aspiration previous to rupture.—Bushnell, *American Journal of the Medical Sciences*, vol. cxii., No. 4.

Amputations at the Knee-Joint.—The first mention of the removal of the leg at the knee-joint dates back to 1581, when such an amputation was made by Fabricius Hildanus. The method then seems to have been lost until 1764, when it was again brought to light by Hoin and endorsed by Petit and Brasdor. It was not, however, until Velpeau popularized it in 1830 that it began to approach the place which it now holds in the domain of surgery. The first American operation by this method was that of Dr. Nathan Smith, in 1824. The advantages claimed for amputations at the knee are as follows: The medullary cavity is not opened, and there is less shock; the attachment of the muscles is less interfered with; there is less retraction, and therefore less liability of the formation of a conical stump; the muscles are not divided through the parts which are thick and vascular, but through their tendinous insertions; the stump is left longer than by a thigh amputation; the stump produced is capable of bearing the weight of the body upon its extremity.—Dr. Buechner, at the meeting of the American Academy of Railway Surgeons, September, 1895.

Dimensions of Bandages.—Bandage one inch wide, three yards in length, for bandages for the hand, fingers, and toes. Bandage two inches wide, six yards in length, for head bandages and for the extremities in children. Bandage two and one-half inches wide, seven yards in length, for bandages of the extremities in adults; a roller of this size is the one most generally used. Bandage three inches wide, nine yards in length, for bandages of the thigh, groin, and trunk. Bandage four inches wide, ten yards in length, for bandages of the trunk.—Henry R. Wharton, "*Minor Surgery and Bandaging*," p. 17.

Varicose Veins.—Trendelenburg's operation is modified by Dr. Moore (*Intercolonial Medical Journal of Australasia*) in the following way: 1. Site of ligature. As the operation aims at preventing reflux of blood into the saphena vein and its branches, this object is better attained by ligaturing above the junction of any of the branches belonging to the lower extremity. 2. Direction of the incision. This is almost transverse, in accordance with the lines of cleavage of the skin in that locality; the edges of the skin come into apposition more readily than do those of a longitudinal incision, and the vein is more easily found in an incision running across it. 3. Ligature material. Silk is more suitable than any animal ligature; only a fine thread is required, and it can be made aseptic with certainty. He adds that being more certainly made aseptic, and less liable to give way, silk is more suitable for out patients who go home at once. The latter proceeding he does not advocate, but is prepared to defend, as it enlarges the province of the out-patient surgeon, when beds are limited.

Hypnotic Anæsthesia.—Dr. Keyes (*American Journal of Obstetrics*, September, 1896) thinks the greatest application of hypnotic anæsthesia will be found: 1. In cases of inebriety and of organic disease in which chemical anæsthesia would be dangerous. 2. In parturition. 3. To relieve by hypnotic suggestion, at the time of an operation, the nervous disturbance and reflex neuroses caused by certain pathological conditions. 4. While performing minor operations upon children. 5. As an aid in the production of anæsthesia by chloroform and ether, as suggested by Davis (*Journal of the American Medical Association*, October 5, 1895), to allay the excitement occurring at the beginning of anæsthesia, and to obviate the necessity of holding the patient upon the table by force.—*Memphis Medical Monthly*, November.

Therapeutic Hints.

Advanced Stages of Pulmonary Tuberculosis.—

℞ Guaiacol	10
Eucalyptol	8
Carbolic acid	6
Menthol	4
Thymol	2
Oil of clove	1
Alcohol (90 per cent.)	170

Mix and dissolve.

With this liquid spray the atmosphere of the room plentifully and frequently.—*Revue de Thérapeutique.*

Hysteria in a girl of eight years was cured by suggestion and she was caused to walk after three days' treatment, though she had not done so for eleven months.—*Journ. de Clin. et de Thér. Inf.*, No. 11, 1896.

Diffuse Bronchitis in Children.—Whenever the rectal temperature, taken every three hours, reaches or passes 102° F., put the child in a bath at 101.5° F., leaving him in the water seven to eight minutes, keeping the head wet with water at the temperature of the room. When the child is over two years a little champagne or brandy and water is given in the middle of the bath, and he is wiped rapidly with hot towels.—Renaut.

Anal Pruritus in bicyclists is treated by alcoholic lotions, frequent change of linen, and in severe forms the application of caustic-potash solution.—Taylor.

Lepra.—Crocker has reported two cases which were greatly improved under hypodermic injections of perchloride of mercury. The remedy is not new in this affection.

Viburnum.—When pregnancy is once established in a uterus whose structures have at times been the seat of inflammatory processes, a prophylactic treatment in the interest of the child and the one which happily tends to ameliorate maternal suffering should be instituted at once. The medicament which most nearly fulfils all the requirements in such cases is found in the fluid extract of Viburnum prunifolium which is well suited for continuous administration. This remedy, although not an ideal one, is, nevertheless, capable of exercising a beneficent influence over the female generative system.—Basham.

Pilocarpine has been suggested and employed as a prophylactic in diphtheria by Shikai (*Wiener med. Presse*). He injects in infants less than a year of age, five drops of a one-per-cent. solution three times daily and ten drops in those of one year of age. These doses are well tolerated, he claims, when continued for two or three weeks. His observations tend to demonstrate the efficacy of the procedure in epidemics of the disease.

Suppuration of the Middle Ear.—A mixture of powdered resorcin and boric acid (1–20 or 1–10) has been used with brilliant results.—G. F. Butler.

Diabetes.—Dr. Moussé has come to the conclusion that antipyrin should not be prescribed for diabetes. Beer yeast was also of no avail in his hands. Loss of weight seemed to be retarded by the use of pancreas, but aside from this it had given him no good results. —*La Semaine Médicale.*

Actinomycosis of the skin, involving the left side of the face, was treated with doses of iodide of potassium, ranging in dose from four to fourteen grams per diem. The infiltrated areas began to disappear and small abscesses opened spontaneously and then quickly healed. Subsequently an otitis media developed with consecutive phlegmon of the face upon the same side. Under the iodide treatment administered per rectum in dose of two grams daily, cure resulted, with three small fistulous openings remaining when the patient passed from observation.—Kozerski, *Medycyna*, No. 24, 1896.

Elixir de Pepto-fer.—

℞ Chloro-peptonate of iron	100 gm.
Alcohol (90 per cent.)	150 "
Simple syrup	400 "
Distilled water	q. s. to make a litre.

Aromatize as desired.

—*Gaz. Hebdom*, No. 92.

Bronze Medal Cure of Cancer.—The daughter of the principal notary of Piacinza, Italy, was found to have in her stomach an accumulation of medals of a Madonna locally celebrated for powers of cure in cancer. She had swallowed a medal each day for a week on advice of her confessor.—*The Churchman.*

Musk is highly esteemed as a medicine in China. It was formerly in repute in many civilized lands, and is still somewhat employed here.

A Tartar Doctor, when he finds himself without his drugs and medicines, is not in the least embarrassed. He writes the names of the needed drugs on slips of paper, and these, being rolled up in little balls, are swallowed by the sick man. "To swallow the name of a remedy, or the remedy itself," say the Tartars, "comes to precisely the same thing."—Noah Brooks.

Sanguinarine Nitrate was the preparation meant in a recent "hint" instead of sanguinaria. It is unofficinal and the dose is given as from one-twelfth to one-eighth of a grain.

Emmenagogue (Dewees' Mixture).—

℞ Tr. guaiaci ammoniatæ	℥ vi.
Tr. ferri chloridi	℥ iss.
Tr. cantharidis	♏ xlviij.
Vini aloes	℥ vi.
Alcoholis	q. s. ad ℥ iij.

M. S. Teaspoonful in milk after meals.

The proportions of this formula must be modified for the individual case. The aloes should be increased or lessened, as may be required, until the patient has one or two softish stools each day. There is also much difference in the irritability of the bladder in relation to cantharides.

Stomachic Tonic.—

℞ Acidi nitro-hydrochlorici	℥ ij.
Aquæ	℥ iss.
Strychninæ sulph	gr. i.

Misce et adde

Tr. gentianæ comp.,	
Tr. cardamomi comp	āā q.s. ad ℥ vi.

S. Dessertspoonful in water after meals.

—Drs. Woods *and* Fitz.

Internal Balneation in typhoid is recommended by Duchesne, who gives inert liquids of various kinds to his patients in such quantities as they may be induced to drink. In thirty-one cases there were but two deaths.—*Gaz. Méd. de Liége.*

To Check Secretion of Milk.—

℞ Hydrochlorate of cocaine	5 gm.
Water,	
Glycerin	āā 50 gm.

Apply five or six times daily.

—Jorie.

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

THE FELLOWS' MEETING AT THE COLLEGE OF SURGEONS—"THE TIMES" ON HOSPITAL REFORM, ETC.—THE PEERAGE OF LISTER—DISCUSSION ON THE PLAGUE AT THE EPIDEMIOLOGICAL SOCIETY—ADULTERATION ACT—FEEBLE-MINDED CHILDREN.

LONDON, January 8, 1897.

THE half-yearly meeting of the fellows of the College of Surgeons was held in the college on Thursday. Mr. Macnamara, vice-president, took the chair in the absence of the president, Sir William MacCormack, who is away from town to recruit after his severe illness. The meeting was a fiasco. After some preliminary business, Mr. Timothy Holmes moved a resolution, calling attention to the reports of the General Medical Council, and asking whether the representative of the college council had correctly construed his instructions respecting the case of Mr. R. B. Anderson. Mr. Holmes did not wish to find fault with the representative, Mr. Bryant, but could not agree with the observations of that gentleman when the matter came up, for he had said there could be "no further action in the law courts." Yet Mr. Bryant had been requested by resolution of the college council "to forward in every way feasible the objects of the civil-rights committee in the case of Mr. Anderson." But Mr. Bryant would surely not say his council had set themselves in opposition to the law. Mr. Anderson is still seeking aid to prosecute his appeal, and Mr. Bryant's course must be damaging to him, not helpful. Mr. Bryant, too, had assumed that the question at issue was not one of principle, and yet it is as such that Mr. Anderson has hitherto fought it and the civil-rights committee has endorsed it. Mr. Holmes appealed to Mr. Bryant as to whether his speech was in accordance with his instructions or could possibly help the cause he was to advocate. The chairman said Mr. Bryant had not been "instructed," but was "requested to forward the matter in every way which to him seemed feasible." You see how he did this. To me, it would have seemed quite feasible for him to hold his tongue rather than make so injurious a speech. The resolution was defeated by ten votes against to nine in its favor.

Mr. Rivington then moved a resolution asking the council of the college to sanction a grant in aid of the Anderson appeal, seconded by Mr. Holmes. Then rose Mr. Christopher Heath to oppose, and he began by asserting that he sympathized with Mr. Anderson, who had "got into bad hands" and they used him as "a convenient stick to beat the council of the college." He maintained that a grant would be illegal, and "nothing would induce him as a treasurer to sign a check for such a purpose." This and more to the same effect he stated, and expressed astonishment that "Mr. Holmes, who as treasurer of a hospital knew what it was to deal with public money, should support such a resolution." Finally, he declared that "a ring was got up round Mr. Anderson against the council of the college, and the time had come for some one to speak plainly." Assuredly, bluff Chris may be trusted to do that, both in words and manner, when he is roused; but bluster is a poor weapon to meet the quiet manner and slight if satirical smile with which sarcastic Tim is apt to drive home his logic. Whether a grant would be legal or illegal would seem a question for counsel learned in the law, and the college might satisfy its members by obtaining such an opinion, instead of putting up the treasurer to throw out suggestions which, Mr. Holmes informed him, "were undeserved and ought not to have been made."

Here it was found that a quorum was not present, and so the meeting ended in a fiasco.

The Times has lately evinced more interest than usual in medical matters. Thus it has published letters about fees, one of which proposes two grades for consultants, a senior and a junior, and suggests such consultation to settle the diagnosis, after which the writer—Dr. B. Squire—thinks a general practitioner would be competent to treat the case. I fancy most general practitioners will exclaim: "Thank you for nothing, Dr. Squire;" or ask him if he wants to be a senior or junior. *The Times* has also spoken on hospital reform to this intent: "Nothing is more curious than the way in which persons who would be ashamed either to ask for charity in any other form or to receive it, feel no compunction in entering a hospital where their board and lodging are paid for by the subscribers;" and further: "Of the out-patients a considerable number are earning good wages." This is capital, and it is to be hoped the newspapers generally will follow the good example of the leading journal.

A good deal of gush and nonsense is apt to signalize the creation of a new peerage, so I am inclined to excuse most of that which has followed the announcement of Sir Joseph Lister's. It may be well, however, to correct some of the most glaring errors. The present House of Lords is not composed of direct descendants of the Norman barons. In fact, half the members are the creation of modern premiers. There were only 50 feudal barons at the Tudor accession. At the death of Elizabeth there were 56. James I. increased the number to 105, and Charles I. to 135. The number increased through each reign until George I. left them at 216; George II., at 229; George III., 339; George IV., 396; William IV., 456; to which 266 have been added during the present reign. Of course, death and other changes have all the time been at work, so the present roll numbers only 577, and may really be said to be an assembly selected from various classes and for various reasons, among which political service stands first, and wealth is an essential qualification. A few, therefore, have really been selected on grounds of culture, *e.g.*, Tennyson, Thompson, Lister. The two last named have no issue, and the peerages consequently will fail with their lives.

It is only natural that the recent advance of the plague should be discussed at the Epidemiological Society. Accordingly, Dr. Cantlie brought the subject forward in a careful lecture, giving his experience in China. He began with remarks on the many names that have been applied to the disease, none of which he found satisfactory, and so he proposed to add one more, viz., "malignant polyadenitis." There is an objection to this clinically, as one gland only may be manifestly affected, although the majority if not all will be found enlarged at the post-mortem. It seems that cases of "pestis minor" or of "ambulant plague," which were generally considered as distinct, must in future be regarded as mild cases of true plague, as a bacillus, indistinguishable from Kitasato's except by its less virulent action, has been discovered in them. The disease affects animals, and the way in which rats die on its advent is familiar to the public. One family of rats, in fact, inhabits just those territories which are most subject to plague, and it becomes an interesting question how far they are responsible for its spread. The infectiousness of the disease would seem less than popular fear has assigned, and free ventilation with hygienic rules diminishes the danger of exposure; but Dr. Cantlie is still obliged to admit that this danger is considerable. But still greater is that of the dust arising during the cleansing of houses which have been occupied by plague patients.

In the discussion that followed, Dr. Lowson, whose experience extends over more than five thousand cases, said he had never found the bacillus in the soil, although a smaller one, which was always present, had perhaps been mistaken for it. The Chinese sold the clothes of those who died, without disinfecting them—a source of infection, as were some other of their customs. He did not think that the epidemic in rats preceded but accompanied the outbreak among men, only the rats died quicker. The serum of inoculated calves (which displayed some reaction, but in which no bacilli were found) seemed to have some effect on rabbits.

Dr. Manson said non-venereal buboes were very common in the East. In Japan they were seen in "river fever," which may perhaps turn out to be "pestis minor." The cases occurring at sea were probably due to infected clothes unpacked on the voyage. Dr. Washbourn pointed out that the bacilli resembled those of various forms of septicæmia in animals, and that infection might vary, as in anthrax, being sometimes by way of respiration, at others through the skin, or taken in food.

I hear that a bill is being prepared for government to submit to Parliament to amend the adulteration of food and drugs act.

The education department has appointed a committee to inquire into matters affecting epileptic and feeble-minded children.

OUR BERLIN LETTER.

(From our Special Correspondent.)

DEATH AND JUBILEE OF CELEBRATED MEN—TAXATION OF PHYSICIANS—PROPOSED TREATMENT OF UNIVERSITY PROFESSORS — INFLUENZA — HEMORRHAGE FROM NORMAL KIDNEYS—HUNGER CURE FOR CARDIAC DISEASE.

BERLIN, December 31, 1896.

THE old year closed with a sad echo. Du Bois-Raymond, the celebrated physiologist, has been snatched by unrelenting death from his labors. But death, though unrelenting, is not always cruel, and so with this great scientist, to whom the world owes so much, especially in the domain of animal electricity. The last months of his life were full of such suffering and pain that the end was a relief for him. He was a pupil of Johannes Müller, that giant among physicians, whose labors were so vast and of such great importance, and whose school, which numbered among its members such men as Virchow, Traube, and Du Bois-Raymond, has done much to further the science of medicine. Du Bois-Raymond was the first to hold the chair of physiology by itself, his predecessor, Johannes Müller, having been professor of anatomy as well as of physiology up to his death. During Du Bois-Raymond's thirty-six years of professorship, the Physiological Institute grew in importance as well as in usefulness, and has now become an independent and vast department.

It is well known that his entire career was the result of a change in professional calling, for he was at first determined for the theological profession. But after the first term he was so attracted and charmed by Johannes Müller's personality that he changed to medicine. Du Bois-Raymond was a popular professor, and his well-known lectures, "The Limits of Natural Philosophy" and "The Seven Problems of the World," made his name well known and liked by the public at large. In spite of his French name, he was a real German, having been born in Berlin; but the sprightliness of his discourses as well as his animated style of delivery reminded one strongly of his descent.

Yet another great scholar has been taken from us by death—Prof. Joseph v. Gerlach, of Erlangen, the nestor of German anatomists. His accomplishments are part of history. He it was who, late in the forties, following up Theodore Schwann's discovery of the animal cell, placed the study of microscopical anatomy upon a new basis, and opened up new fields for research in that department of medicine. The introduction of the technique of staining in histological work and of the injection of blood-vessels by Gerlach has opened up a new epoch in medicine. His labors have made his name immortal.

Professor von Bergmann has recently celebrated the sixtieth anniversary of his birthday. Although born in Russia, he is numbered to-day among the most celebrated of German surgeons. His reputation as an accurate diagnostician and a most skilful operator extends far beyond the field of his work. It would be superfluous to speak here of his scientific accomplishments; the large number of his present and former pupils which assembled in the auditorium of th University Surgical Klinik upon his birthday proves best that he has done much for surgery. Some of his pupils present upon that occasion were Professor Bramann, Professor Glück, and Professor Rotter, besides many others. Of his admirers who were there might be mentioned the names of Professor König and Prof. Julius Wolff. Von Bergmann spoke that day about brain surgery, a field in which he works with especial love. Before and at the conclusion of his lecture, addresses were held in his honor by former as well as present assistants of the professor, and together they presented him with his portrait painted by Lerbach. Von Bergmann wields a great influence here in medical circles, and knows well how to put in a good word for the rights of the profession. He has called a meeting of those physicians and surgeons who have private clinics. The department of taxes wishes to impose a business tax upon such, although physicians are otherwise exempt from business or professional taxes.

The administration of the Prussian universities contemplates the remuneration of the professors in a manner similar to that now in vogue in the United States. Hereafter, when a new professor shall be appointed, it is intended that he shall not as heretofore receive the entire fees, but he shall receive instead a fixed sum (in Berlin, 4,000 marks). All surplus moneys shall constitute a fund, one-half of which shall be devoted to the payment of the associate professors and other special workers. As this arrangement would naturally increase the power of the minister of education and would place the professors in a certain measure in a dependent position, it is hardly likely that the latter will acquiesce in the proposed scheme. It would very probably result in the well-attended medical lectures and courses proving of vast material benefit to the poorly attended theological ones. At present everything is to remain as it is.

Influenza was again prevalent in Berlin in December. In spite of the rather epidemic character of its present visit—or, rather, because of it, for it meant, of course, employment and fees for the physician—medical life and scientific work continued in a most animated way.

Not only is influenza the main topic for the medical circles, but other questions have also been brought forward for discussion. So, recently, Dr. Klemperer, assistant of Professor Leyden at the Verein für Innere Medicin, delivered an address upon "Hemorrhage from Normal Kidneys." He cited a number of cases from medical literature and from his own experience in which hemorrhage from the kidneys occurred, preceded as well as followed by complete health. In some cases bodily exercise, *e.g.*, riding and marching,

as well as exposure and cold, were given as causes; but at times no etiological factor could be discovered. These are not cases of "hæmophilia renalis," spoken of and described by Senator. The kidneys are just as healthy as, for instance, the normal uterus during menstruation. These hemorrhages take rather the type of hysterical hemorrhages. Klemperer was led to his idea because he found that some kidneys, removed on account of hemorrhage, were perfectly normal. In the course of his remarks he advised practitioners not in every case of renal hemorrhage to conclude immediately that malignant disease must necessarily be present, and therefore to place the kidney as soon as possible under the knife. Still more frequent is the association of hæmaturia with normal kidneys. In the discussion which followed his remarks, the only opponents were the surgeons present, who claimed that by the delay necessarily involved the proper and most favorable time for operation would be lost.

Hirschfeld's address upon the "Mechanical Treatment of Heart Disease" is also worthy of comment. Bodily exercises are indicated in heart disease only when this results from overnutrition, fatty degeneration. The heart dilates as a result of overexertion, and it is necessary through proper training to adapt and accustom the heart muscle to this dilatation. In the stage of broken compensation, "Inanition-therapie" (a pint and a half of milk a day as the entire nutrition), in combination with complete rest in bed, is very advantageous. It is of interest to note that the cardiac dulness of soldiers marching with heavy accoutrement, of wrestlers, etc., is increased. It is to be hoped that now we shall not starve our patients with heart disease, whom heretofore we feared we could not feed enough, for this advice is not to be followed literally in all cases.

DERMATITIS FROM ROENTGEN RAYS.

To the Editor of the Medical Record.

Sir: With regard to your interesting editorial on "Some of the Influences of *X*-, Solar, and Electric Rays upon the Skin" (Medical Record, December 19, 1896), I shall esteem it a favor if you will kindly allow me space to offer a few remarks on the subject.

It has long been known that the obscure heat waves of the electric light are more powerful than the light waves, and further, that they can be absorbed to a great extent by allowing them to pass through a clear solution of alum in water. I need not in this place refer at length to Tyndall's experiments in this direction ("The Forms of Water," eleventh edition, 1892, p. 14, *et seq.*).

I now come to the effects of the *x*-rays on the skin, and at the outset I would ask whether the cutaneous manifestations are really due to the actual *x*-rays themselves, or whether they may not be the result of the action of obscure heat waves developed in the Crookes tube. My experience of the *x*-rays is limited. It is for this reason that I put forward the suggestion in the form of a query. No doubt some of your correspondents familiar with the physics of the subject will favor me in your columns with their views of my hypothesis.

I think I am correct in saying that a certain amount of heat is developed in the Crookes tube before the *x*-rays become manifest; also that heat is developed during the whole of the time the sparks are produced.

In the recorded instances of dermatitis following exposure to the *x*-rays, the exposure of the parts affected was either prolonged, as in the case of skiagraphing the spine, etc., or it was repeated at frequent intervals, as in the case of those patients employed in demonstrating the Roentgen rays. The appearances in the one case I have seen, belonging to the former group, were those of a burn.

The question can perhaps be settled in the following way, viz.: By experimenting with a patient previously affected, with a solution of alum in water placed between him and the Crookes tube. In this way the obscure heat waves might be absorbed, without interfering with the *x*-rays, which Sir Gabriel Stokes and Lord Kelvin are inclined, I believe, to regard as a form of light.

These views are purely hypothetical, but I shall take the earliest opportunity of putting John Hunter's precept into execution, viz., trying it experimentally.

George Pernet, L.R.C.P. Lond., M.R.C.S. Eng.

London, December 31, 1896.

P.S. It would also be interesting to pass the *x*-rays through a solution of iodine, and note the result.

PUBLIC AND PRIVATE MEDICAL CHARITIES.

To the Editor of the Medical Record.

Sir: In reply to the letter of Dr. Sturgis in your last issue, I would call attention to the fact that the public purse is spared an enormous drain by a system of private benevolence to which only a minute proportion of our moneyed men contribute. As a tax-payer, Dr. Sturgis would be in a sorry plight if his line of argument were pushed to its legitimate conclusion. For if he complains that a tithe of the cost of maintaining certain charities falls upon the city, how would he feel if the entire cost were added to the annual budget!

It is estimated by those familiar with the subject that there are in this city only some four or five hundred persons to whom one could apply with any hope of success for any charitable object. The rest are perfectly willing to stand by and see these bear a burden of which they themselves will not voluntarily carry a straw's weight, however ready they may be to contribute lavishly to the ruling folly of the hour. By judicious appropriations of public money in aid of so-called private charities (private as to the givers, public as to the recipients), these people are made to do a small fraction of the duty they habitually shirk, and at the same time a vast amount of private aid is made available for the public good and the relief of the taxpayer.

Lest Dr. Sturgis elect to assume for the city the entire burden of the work done by the charities he assails, the intelligent taxpayer will prefer to encourage private benefactions by a relatively small amount of public aid, well knowing that the investment so made will save many times the amount to the public treasury.

Andrew H. Smith, M.D.

To the Editor of the Medical Record.

Sir: I wish to make a reply to a letter which appeared in your columns on the 16th of January, entitled "A Matter of Interest to Medical Taxpayers." I do not desire this for the purpose of entering upon any continued controversy with the author of the letter or with any other persons, but because I fear, judging from the tone of the leading article in your columns, entitled "Public Money for Private Uses," which appeared on January 2d, that there may be others besides the writer of this article and of the letter who do not correctly understand the matter in hand, and who, therefore, do not state the facts as they are believed to be by the directors of one, at least, of the so-called

"private medical charities" of this city reflected upon in these articles.

At the outset, I beg to state that it is a mistake to call the New York Post-Graduate Medical School and Hospital a private institution, unless various qualifications are made. We have a special charter, granted, after encountering much difficulty, by the legislature of the State of New York in 1886. We are under the supervision of the board of regents of the university, and are a part of that great body which includes all the public educational institutions of the commonwealth. Besides this, under the new constitution, we are also responsible to the State board of charities, to whom we make regular reports of our financial condition. To call us a private institution, in the sense that a boarding-school or a private hospital is one, or as the medical colleges of the State, with two or perhaps three exceptions, are, is certainly incorrect. We are not even a private institution in the sense that the New York Hospital or Roosevelt Hospital is. Their directors may be said to have supreme control over their own affairs, without any such supervision as that I have just indicated. Your correspondent objects to us because we are a "teaching body," and, consequently, become so much the less a charitable institution. With that view I take issue. The Post-Graduate Medical School and Hospital, as a teaching body, is in the highest sense a charitable organization. The professors and instructors of that body have never been organized into a stock company. Not only have they never received any dividends from the investment of their time and money, which have been freely contributed, but they have never supposed they would get any. At the present moment all the fees received from physicians are turned into the hospital. This action is in accordance with the spirit in which the institution was founded. This spirit involved the establishment in the city of New York, on a firm basis, of a college in which doctors of medicine might be further instructed in the knowledge they had acquired in undergraduate schools and in practice. The founders knew perfectly well that no enduring institution could be established if it were made a private or business affair—a stock company; hence the special charter; hence the voluntary placing of ourselves under the direction of the State authorities; hence the provision that a board of directors, not necessarily members of the faculty, should govern the whole institution, and that the professors should merely be engaged in teaching: hence the understanding that, until the institution was firmly founded, these teachers should not receive any salaries. When the college is firmly planted and amply endowed, no doubt the professors will receive salaries from the directors, just as they do in the College of Physicians and Surgeons and in other medical, scientific, and academic institutions which are not stock companies, but, like the Post-Graduate, public institutions of learning. This is a point that the Post-Graduate Medical School and Hospital has many times endeavored to make clear to the public and to the medical profession. But it now seems necessary to make another statement of the facts, although they have been many times printed and published far and wide. It is not true that this medical institution, "with a hospital attachment," is not primarily a benevolent or charitable institution. It is both primarily and secondarily so.

Now allow me to state the facts about the annual appropriation of $30,000, for which we shall continue to ask until the law allowing the board of estimate and apportionment at its discretion to give us that sum is repealed. The Post-Graduate Medical School and Hospital asked for nothing from the State until we had invested much more than half a million of dollars in a plant, land, and buildings, until we had spent twelve years in unremitting labor, encountering the most varied obstacles, during all of which time we had contributed all of the fees received for instruction to the establishment and maintenance of the dispensary and hospital. This thing of asking for State aid was not done in a corner. We went to the legislature of the State of New York in 1894, and asked for an appropriation of $30,000 a year, as has been said, to be given at the discretion of the city board of estimate and apportionment. A bill granting this passed the legislature, was commented on in the public press, went to the mayor of the city of New York, received his approval, without which it could not have been a law, and was finally, after full consideration, signed by the governor. It is remarkable that the "medical taxpayers" whom your correspondent desires to represent did not take advantage of any of these opportunities to oppose the bill. At the same time with the passage of the law allowing us $30,000 a year, there was one passed allowing the Society of the Lying-in Hospital of the City of New York $12,000 annually, and I think there were other institutions similarly favored. We then supposed, in view of the circumstances of the case, the work we had done for the city, for the State, and for the country, that we should have no difficulty in securing the allowance of the full amount of $30,000; but this was opposed, not by any body of the taxpayers, but by one member of the board of estimate, and consequently last year this sum to be granted was fixed at $15,000. The board of directors then determined that if this cutting down of the sum asked for were to be repeated this year, it should not be without a full statement of our claims and our needs being presented to the municipal authorities. We therefore were represented by several members of our board at the meeting graphically described by your correspondent, and succeeded in convincng the whole board that, under all the circumstances, we ought to receive at least $20,000. Even the two members who voted against us in the beginning finally concurred in this view, for, as I understand the matter, no appropriation by the board of estimate is valid unless it be made unanimously. It has been shown in another place[1] that these reflections upon institutions like our own are not in consonance with the spirit or letter of the new constitution of the State. It is manifestly impossible for the State to provide adequately for medical education and the care of the sick in New York without private aid. This is given to various hospitals and teaching bodies as well as our own, but it is notorious that, except in the Hospital Saturday and Sunday collections, there is no general giving by the public for the hospitals of the city. A few hundred of our fellow-citizens give all that is given for the support of these great institutions, without which New York City would be as cruel to the sick and disabled as if it were a barbarous community. The municipal and State aid is merely giving one dollar to supplement the hundred dollars or even more given to the same institutions by private charity. The legislative precedents are all in favor of the State aiding such a college and hospital as ours. The New York Hospital, after many liberal gifts from the State, received a share of the sum raised by taxes in the city of New York from 1806 to 1859—$12,000 a year; the University Medical College received a subsidy of, I think, $3,000 a year, for a certain number of years. Bellevue Hospital Medical College held its sessions, until the recent fire, in a building on the city grounds, for which they paid rent, erected for them by the commissioners of charities and correction. The public hospitals under the care of these commissioners are provided with ample arrangements for teaching medicine. If we turn to the State of Pennsylvania, we find that a

[1] Post-Graduate, January, 1897.

very different view of the claims for State aid of benevolent and charitable institutions exists there than obtains in the mind of your correspondent, and, perhaps, in that of the MEDICAL RECORD. That State has for years granted a subsidy to its medical colleges, and to all of them hospitals are attached. In so doing, I believe it has done a great service to the taxpayers. The matter of the propriety of State aid to worthy medical schools and hospitals is to me beyond argument. We have nothing to apologize for in asking for it.

If the directors of the Post-Graduate Medical School and Hospital, in applying for and accepting the money from the State to carry out their legitimate and beneficent objects, are "well-dressed mendicants," we did not become well dressed from dividends or salaries from our institution, and we are mendicants for a real charity, of which we are not ashamed. We believe we ought to be assisted until we are firmly established, and then, depend upon it, we shall not ask for aid. The money we receive is characterized by your correspondent as "plunder." This is a very harsh word. Plunder is money or valuables taken by force or by fraud from an enemy. I think your correspondent will ultimately regret that he applied such a term to the aid received by us from the State. I deny the existence of anything that would justify any such language being used with reference to our institution, and I am very much surprised that any member of the medical profession, with any knowledge of our methods and work, could so use it. I am also surprised that your great journal should publish, in a leading article, that which seems to invite such attacks upon us as the one which I have been criticising. The Post-Graduate Medical School and Hospital is doing much more for the city and State than they are doing for it. We have always been willing, as suggested in your leading article already referred to, to present and have presented our "special claims fairly and squarely before the public, as a proper preliminary" for our applications for money. We challenge the most careful scrutiny on the part of the most judicially minded members of the medical profession as to the aims and work of the school and hospital in every particular. In spite of the views of your correspondent, I am happy in the belief that we have the confidence of the mass of that profession from Canada to Texas. Very respectfully,

D. B. ST. JOHN ROOSA, M.D.,
President, New York Post-Graduate Medical School and Hospital.

January 23, 1897.

The Hamilton Decalogue.—The following terse sayings are attributed to the late Dr. Frank H. Hamilton: "1. The best thing for the insides of a man is the outside of a horse. 2. Blessed is he who invented sleep; but thrice blessed the man who will invent a cure for thinking. 3. Light gives a bronzed or tan color to the skin; but where it uproots the lily it plants the rose. 4. The lives of most men are in their own hands, and, as a rule, the just verdict after death would be—*felo de se*. 5. Health must be earned—it can seldom be bought. 6. A change of air is less valuable than a change of scene. The air is changed every time the wind is changed. 7. Mould and decaying vegetables in a cellar weave shrouds for the upper chambers. 8. Dirt, debauchery, disease, and death are successive links in the same chain. 9. Calisthenics may be very genteel, and romping very ungenteel, but one is the shadow, the other the substance, of healthful exercise. 10. Girls need health as much—nay, more than boys. They can only obtain it as boys do, by running, tumbling—by all sorts of innocent vagrancy. At least once a day girls should have their halters taken off, the bars be let down, and be turned loose like young colts."

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending January 23, 1897:

	Cases.	Deaths.
Tuberculosis	165	98
Typhoid fever	11	6
Scarlet fever	164	13
Cerebro-spinal meningitis	5	7
Measles	118	5
Diphtheria	288	28
Laryngeal diphtheria (croup)	3	3
Chicken-pox	24	0
Leprosy	1	0

Albuminuria Minima is self-explanatory and less misleading than such names as intermittent, cyclic, and functional. The albumin is probably always present, but in such small amounts as to escape detection.—TALAMON.

Cold Bathing during menstruation is a beneficial measure, provided women become accustomed to it by bathing every day for eight days before. Hehzel holds that cold salt-water baths facilitate the menstrual flow, increase the duration of genital life, and increase fecundity.—DEPASSE.

The Physician's Own Health should be more carefully looked after by the doctor, according to Dr. Kortright in the *Brooklyn Medical Journal*, who finds that most physicians overwork and are prone to the development of arterio-sclerosis. Ambition should be curbed and contentment should come with a small or moderate practice. Plenty of walking and outdoor exercise are recommended and regular vacations.

Books Received.

While the MEDICAL RECORD *is pleased to receive all new publications which may be sent to it, and an acknowledgment will be promptly made of their receipt under this heading, it must be with the distinct understanding that its necessities are such that it cannot be considered under obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

CLINICAL OBSERVATIONS ON CONVULSIONS IN THE ADULT, WITH DIAGNOSIS AND TREATMENT.

BY WILLIAM H. McENROE, M.D.,

NEW YORK.

IT is not an easy task to classify the various forms of convulsive disorders occurring in the adult, for the reason that they are due to many different causes, some of which are local or general, acute or chronic, or even purely functional. Convulsive movements are usually associated with various changes in the brain and nervous system. They are caused by cerebral hemorrhage, intracranial tumors, traumatic injuries to the head, embolism, specific gummy tumor, chronic renal diseases, puerperal eclampsia, epilepsy, hysteria acute and chronic, insolation, and by the poisonous action of certain narcotic drugs. Convulsions are caused by some irritation of the motor tract, and this may be direct or indirect, as in the case of a reflex spasm. When the contraction lasts for a short time only, and is followed by relaxation, the condition is called clonic spasm. When the contractions are persistent, with continuous rigidity of the muscles, it is known as tonic spasm.

These conditions may be present in the same muscle or in a group of muscles, and may alternate with each other. When this alternate contraction and relaxation becomes very rapid and fine it is called tremor. This is an important symptom of many convulsive disorders. It may depend on organic lesions, such as tumors, sclerosis, and degenerative changes in the brain and cord. The senile tremor occurs with advanced age, but is rarely seen before seventy years. This tremor at first takes place during voluntary movement only. Later on it occurs at all times, even during sleep. The hysterical tremor may be either a coarse or a fine one. In the case of the former there is rhythmical contraction and relaxation having no relation to voluntary movement. In the latter case the tremor always occurs during movement, and is decidedly irregular. The toxic tremor is produced by the poisonous action of alcohol, tobacco, lead, mercury, opium, and chloral. Tremor is a constant symptom of paralysis agitans and chorea. Fibrillary twitching often accompanies general paresis, tetanus, strychnine poisoning, and acute meningitis of the brain and cord.

Motor paralysis exists in all degrees of intensity, from the slightest perceptible weakness to the total abolition of muscular power. When the loss of power is very slight, the word paresis is designated to express it. The term paralysis indicates total loss of muscular power. Hemiplegia or paralysis on one side of the body often accompanies convulsive diseases. It is a constant symptom of apoplexy and embolism and may be due to many other causes, some of which are purely functional. When hemiplegia is caused by cerebral hemorrhage, the lesion is usually found in the corpus striatum on the left side. This is accompanied by right hemiplegia with loss of speech. Lesions occurring in this particular portion of the brain cause special disturbances of speech, which are called collectively aphasia. It should be borne in mind that aphasia is not a paralysis of the muscles of articulation and phonation, but that it is due to the inability of the speech centre to select the correct word and cause the necessary muscular movements for its pronunciation. The muscles of articulation and phonation are perfectly intact, but the patient cannot speak at all, or he may be able to say a word or two. Very often there is agraphia or inability to write, and sometimes alexia or inability to read. If the lesion occurs in the centripetal path of the auditory nerve there will be word deafness or sensory aphasia. The hearing for sound is perfectly good, but the sense of differentiation of words is lost. Lesions of the supramarginal and angular convolutions produce a condition of mind blindness, known as apraxia, in which the patient, while he sees objects, fails to recognize their nature or shape by vision. In left-handed persons the speech centre is situated in the right side of the brain: therefore in these cases there is left hemiplegia with aphasia. Very often the muscles of the arm and leg are affected. If the face is involved, there will be retraction of one of the angles of the mouth, which is drawn toward the healthy side. When hemiplegia is uncomplicated, the diagnosis is easily made. If coma is present, the diagnosis is very difficult and sometimes impossible.

There is a number of symptoms that are invariably associated with convulsive diseases, which require a detailed description. These consist of certain sensations which some persons experience, preceding or at the moment of attack. This is notably so in epilepsy, in which the phenomenon is known as an aura. Strictly speaking, this term refers to the sensation of a draught of air blowing upon the surface of the body and gradually passing upward to the head. However, as this symptom is not a common one, the term is now used to indicate any feelings that may be experienced by the patient preceding the attack. This very often consists of a creeping or numb-like sensation, beginning in the fingers, or even in the toes, and rapidly passing upward. In other instances there is a marked disturbance of the vasomotor system. The arm or the leg may be pale in color and cold to the touch, and the sensibility of the skin greatly diminished. There are often profuse perspiration, with a great flow of saliva, and fibrillary twitching of the muscles of the face and eyes. There is perversion of one or more of the special senses, often taking the form of a very sweet or bitter taste in the mouth; even ocular illusions may occur. One of my patients invariably saw a white dog cross his path, immediately preceding the attack.

Epilepsy.—There are two well-known forms of epilepsy which may occur alone or even together in the same person. They are called epilepsia gravior or *le grand mal*, and epilepsia mitior, or *le petit mal*. The former is the most common, and its symptoms constitute what is known as an epileptic fit. It is usually ushered in by an agonizing cry, which at one time was supposed to be due to pain or to fright. It is now known, however, that this cry is due to the spasmodic action

of the laryngeal muscles, by which action the air is forcibly expelled through a constricted orifice. The cry itself is very diagnostic of epilepsy. Coincident with this, the jaws become suddenly clenched and the tongue is very often bitten. This is a very important sign, especially when the attacks take place during the night, of which the patient is quite unconscious, and thinks, perhaps, that he has had a fainting-spell. But whenever the tongue has been bitten, it indicates that there has been a severe attack of convulsive epilepsy. The face is generally pale at the onset, but on account of the violent contraction of the muscles of the neck, and the pressure exerted on the great veins, turgescence rapidly follows. Respiration for the same reason become gasping in character. The patient appears to be strangled. If he is standing he falls down. Unconsciousness is complete and the muscles are in a state of tonic contraction. The eyes roll around, the pupils are dilated, and the pulse is rapid. This condition lasts for about one-half a minute and is then followed by a state of clonic muscular spasm, by which the whole body is thrown into the most violent agitation. The eyes roll around wildly. Mucous foam mixed with blood collects in the mouth. Sometimes the sphincter muscles are relaxed, and there is incontinence of urine and fæces. This stage lasts for a few seconds to several minutes, when the convulsions begin gradually to subside, the muscles become relaxed, the patient returns to partial consciousness and may attempt to speak. Soon after, however, drowsiness and stupor supervene and may continue for several hours, the patient returning to a conscious state with a feeling of exhaustion, and usually with some expression of surprise. This constitutes the convulsive form of epilepsy, and is regarded by many as the only true form of that disease. But, unfortunately, this malady may occur without any convulsions whatever: therefore it is incorrect to define it as a convulsive disease. The other manifestation of epilepsy to which the name *le petit mal* is given differs from that form already described, as stated, by the absence of convulsive movements. There is slight pallor of the face. The patient rarely falls, never suddenly. The symptoms are all slight. The patient recovers quickly from the attack, a little depressed and with a tendency to excessive micturition. During conversation he may suddenly turn pale, stop for a second or two, and then resume again, without being aware of anything having happened. This is not a simple disease, as the name implies, but is far more destructive to the mental powers than in the violent convulsive form.

The above account gives a fair representation of the phenomena usually found in the two varieties of epilepsy, but I must confess that many cases exhibit symptoms that cannot be included in such an account. There is a form in which consciousness is not lost, and many actions are performed that would indicate voluntary movement, but these are to a limited extent only, and resemble the actions of a somnambulist. This form is known as co-ordinate epilepsy. In another variety the patient soon after the attack is suddenly seized with a homicidal mania, of which he subsequently remembers nothing. Epilepsy seems to exert no particular injury to the bodily health, and I have known cases of severe convulsions to be accompanied by a fair degree on bodily nutrition. It is quite different, however, in regard to its influence on the mind. There are many cases on record of epileptics having been suddenly seized with an irresistible desire to do bodily harm, or even to the commission of heinous crimes against themselves or others, so that powerful physical restraint is sometimes necessary to prevent them. This condition is known as epilepticus furor, and, strange to say, these attacks are more often associated with *le petit mal*.

Uræmia.—There is a convulsive disorder that so closely simulates an epileptic seizure that it is exceedingly difficult to distinguish one from the other. This condition is produced by the retention of poisonous products in the blood which under normal conditions are excreted by the kidneys. The primary cause here is the failure of the kidneys to perform their natural function of elimination. This may occur during the course of any disease in which renal suppression takes place, and therefore may occur as a complication in all the forms of Bright's disease, but it is more likely to take place in the acute form. It also occurs in the puerperal state, after operations on the urethra, in diseases of the bladder, and in malignant and suppurative renal diseases. A number of premonitory signs and symptoms precede an attack of uræmia. There is œdema in various parts of the body, notably in the face and underneath the eyes. The patient is drowsy and stupid, and may have headache, vomiting, diarrhœa, and black spots before his eyes. The pupils may be contracted, but not symmetrically so, or one may be contracted and the other dilated, or both may be dilated. There is one characteristic sign: the pupils will not react to light. The face is pale, waxy, and dingy in appearance, and the hands are very white. The pulse is changeable. It is accelerated during the spasm, but afterward falls to normal or even lower. It is also incompressible. If rigid arteries are present under these conditions, the diagnosis of uræmia is positive. The urine is diminished in quantity, of high color, and contains albumin, blood, and casts. The attack may consist of one paroxysm: more often there are several, following each other at intervals of a few minutes or many hours, the patient meanwhile lying in a condition of profound coma. The attack itself closely simulates an epileptic seizure, and great care must be exercised in making a diagnosis. The initial cry of epilepsy is wanting. The œdema and swelling are characteristic of uræmia. In many cases there is a strong odor of urine from the surface of the body. The temperature is generally elevated, sometimes as high as 107° F. A low temperature may occur, but usually in old persons. The patient may pass into coma, and this is always accompanied by stertorous breathing. This has a harsh hissing sound, resembling a whistle, which is caused by the expired air rushing against the hard palate and teeth. The respirations are increased at first, later on they are diminished and become very heavy and labored. The patient is absolutely comatose and cannot be roused. Unless the coma is very profound, there is usually twitching of the muscles of the face and hands. The respirations are always modified in chronic nephritis. There is paroxysmal dyspnœa, especially at night; Cheyne-Stokes respiration may continue even through the comatose state. I have never seen hemiplegia follow an attack of uræmia. In epilepsy reflex sensibility is constantly present and absent in uræmia. Following the paroxysm in uræmia the patient passes into profound coma. There is only a deep sleep after an epileptic fit, from which the patient can be roused. In epilepsy one side of the body is more violently convulsed than the other; both sides are equally affected in uræmia. Nystagmus is sometimes observed but occurs more often in puerperal eclampsia —a condition that will now be described. It occurs most frequently in young women, or in those who are pregnant for the first time. These convulsive movements are often started up by some local irritation and sometimes by mental depression and worry. Severe headache, usually confined to one side of the head, is a prominent symptom. Black spots before the eyes, amaurosis, and impairment of memory may occur. Œdema is always present, involving the subcutaneous cellular tissue of the face and upper extremity. Dur-

ing the attack the patient is absolutely unconscious, and reflex sensibility is totally suspended. These spasms usually occur before labor, during labor, or after labor. In all cases large quantities of albumin and casts are found in the urine, and sometimes the kidneys are acutely inflamed. The attack is sudden in its onset, and resembles in every respect a severe epileptic convulsion; even the involuntary muscles are affected, leading to temporary arrest of respiration, producing a partial asphyxia. The attacks are of short duration, as a rule. After the first attack, the patient regains consciousness but is confused and drowsy, and has no conception of what occurred. If the spasms are repeated, the patient goes into profound coma during the intervals, and death may take place at any time. During the convulsion the pulse is greatly accelerated, running up to 140 or 150 per minute. Now, in fevers this pulse is not necessarily fatal, but it is so here, because the pulse is not only strong and rapid but it is incompressible, and something must be done, for this condition is one of the greatest danger. We must not overlook the fact that a pregnant woman may be an epileptic, or she may have an hysterical convulsion, or even be stricken down with an apoplexy, all of which give rise to symptoms similar to those of eclampsia. This disease, however, has a definite history that is quite different from that of any one of those conditions mentioned, and with the albumin and casts in the urine of a pregnant woman the diagnosis is never doubtful.

Apoplexy.—Cerebral hemorrhage or apoplexy is in a large number of cases caused by degeneration of the walls of the arteries of the brain. In the majority of cases the hemorrhage is from the branches of the Sylvian artery, which are given off in the anterior perforated space and are distributed to the corpus striatum and the internal capsule. Periarteritis, leading to sclerosis and the production of miliary aneurisms, is one of the most frequent causes of intracranial hemorrhage. These little bodies are found involving the arterioles throughout the whole substance of the brain, but are more often found in the pons, the lenticular and caudate nuclei, the optic thalami, medulla, centrum ovale, and the cerebellum, and are always the principal cause of very large intracerebral hemorrhage.

Atheroma is another cause of hemorrhage, and leads to the formation of aneurisms of the medium-sized and larger arteries. Left ventricular hypertrophy with interstitial nephritis and arterial sclerosis are common causes of apoplexy. Embolism and syphilis, producing an affection of the cerebral arteries, often give rise to symptoms very similar to that of apoplexy. Age is a very important factor in these cases. Apoplexy more often occurs in persons over fifty years of age, and the younger the patient the more likely is syphilis or embolism.

Now, as regards the phenomenon of an apoplectic seizure. In the majority of cases the onset is sudden, the patient falling down and becoming quickly unconscious, with or without convulsions; as a rule, the pupils are irregular, there is almost always conjugate deviation of the eyes. The face is cyanosed, the pulse is generally of high tension. The respirations are diminished in frequency and stertorous in character. There is hemiplegia or paralysis on one side of the body. In other cases the symptoms are slow in their development, and for the time being the patient does not lose consciousness. There is paralysis and often complete relaxation of the extremities; this is followed by gradual loss of consciousness finally ending in deep coma.

I have found the arm more completely paralyzed than the leg, although in many cases the loss of power is complete in both. Very often the face and arm are affected and the leg escapes.

Coma.—This brings up the subject of coma which is a constant pathological element in many of the convulsive diseases. Coma may be defined as a condition of insensibility with symptoms of brain pressure. No real form of coma can exist unless some portion of the cerebrum is compressed, either directly or indirectly. Coma differs from sleep in that it is a pathological condition, from which the system derives no benefit. The prognosis, as a rule, is unfavorable in proportion to its degree and duration. There is a condition known as syncope, which is due to failure of the cerebral circulation caused by cardiac weakness. This can always be distinguished by the flickering pulse and the condition of the heart, and in no way resembles true coma. In the coma following cerebral hemorrhage the respirations are slow, often irregular, and sometimes rapid. The pulse is usually hard and incompressible. There are hemiplegia and often strabismus, with irregularity of the pupils. The patient is absolutely comatose, and cannot be roused. In the coma of opium poisoning there is symmetrical contraction of the pupils, in many cases down to a pin's head, and this is a very significant sign. The skin is wet with warm perspiration. The respirations are deep and stertorous, and are greatly diminished in frequency, sometimes down to five per minute. The pulse is strong, regular, large, and compressible. The patient can be partially roused and his answers are rational as far as he goes, but he does not finish. In the second stage there is a condition of collapse that usually precedes death. All the symptoms are of profound exhaustion of the respiratory and cardiac centres. In alcoholic coma the face is red and flushed. The respirations are regular and rapid. The pulse at first is strong and rapid, later on it becomes quick and weak. The patient is irritable and can be roused to a drunken consciousness. He is angry at interference and generally swears.

There is another form of coma that is due to concussion of the brain. It is of great importance to recognize this form, as it is often due to criminal assault. There is one very characteristic symptom of this kind of coma. The control of the brain over the spinal cord is withdrawn; therefore its reflexes are set free, and the least external impression leads to twitching, sometimes great enough to shake a whole limb. Therefore wherever there is jactitation it points to some injury of this kind, and should never be overlooked.

Hysteria.—The term hysteria is employed to indicate a large number of nervous phenomena, denoting an abnormal condition of the mind and nervous system. There is an exaggerated susceptibility to emotion, often occurring alternately—for instance, crying and laughing without adequate cause. The patient lays great stress on the various symptoms of disease, for the purpose of exciting sympathy. Hemianæsthesia is a common symptom. Along with this there is paralysis of one or more groups of muscles. Contracture alone, or with paralysis and anæsthesia, usually follows convulsions and may affect one side of the body—the arm or leg, or even the lower extremity. Tympanites is a common symptom and may in some cases simulate pregnancy or even peritonitis. There is rarely complete loss of consciousness. The patient may fall upon the bed or floor, but not in a way to cause injury. The legs and arms are thrown about in all directions. The patients struggle violently and often show prodigious strength. The attacks do not occur when the patient is alone. The respirations are tumultuous and noisy, but there is never danger of asphyxia. Muscular twitching of the eye is common, but there is no divergent strabismus. There is much foaming at the mouth, but the tongue is never bitten. In the minor form of the convulsive movement the contractions are

clonic and irregular, usually lasting for a very short time, and are almost always followed by an emotional attack. There is a sense of pain or fulness in the epigastrium, with the well-known globus hystericus in the throat, the spasm at first involving the muscles of the eye and often passing to the trunk and extremities. The eyes are often turned to persons or objects near by, and then rolled up again. These attacks last for an indefinite time, and are followed by much weakness, but never by stupor or coma.

Hystero-epilepsy is an exaggerated form of the above condition. These attacks are accompanied by the globus hystericus. There are clonic and tonic convulsions very closely simulating epilepsy. The duration, however, is much longer than in the case of epilepsy. After the convulsion the patient is violently emotional. Contortions occur and even catalepsy may be developed. During these severe attacks the patient is generally comatose, assuming various attitudes, but after a time consciousness is restored, often with delirium and hallucinations, the patient in some cases lying in a trance for several days. The convulsive movements may affect the feet and hands only, sometimes consisting of a coarse tremor or even fibrillary twitching. The tongue is never bitten as in epilepsy.

Catalepsy consists of intermittent attacks and suspension of voluntary power and sensation, without convulsions, and is always accompanied by general or partial muscular rigidity, so that the parts involved retain for an indefinite period the position in which they were placed at the beginning of the attack. The most common cause of catalepsy is strong mental emotion. It is sometimes very brief and sudden, and in some cases precedes true epilepsy. In itself it is not a dangerous disease.

Cerebral Tumor.—Convulsive movements are prominent symptoms of the various tumors of the brain, and in some instances closely simulate an epileptic seizure. I have never seen intracranial tumor without double optic neuritis and paralysis of one or more of the cranial nerves. Vomiting and intense headache are always present. The pain, which is exceedingly severe, is situated in the back of the head, with a tendency to radiate forward or to one side. With this there is nystagmus, and in almost every case pathological changes are found in the optic discs. The swelling of the papilla, known as choked disc, is a very diagnostic sign of tumor. The pupils are generally dilated and atrophic changes are almost always found in the optic nerve. Aphasia is sometimes present. This indicates some disturbance of the speech centre, the lesion involving the posterior portion of the third convolution of the left anterior lobe. Persistent vomiting is a very distressing symptom. This is generally caused by pressure or interference in some way with the semicircular canals. Hemiplegia and paraplegia are frequent symptoms of intracranial tumor. With our present knowledge of the motor areas in the cortex it is possible to differentiate the various tumors by a careful consideration of the extent and location of the convulsive movements. Tumors of the cerebellum cause an irregular or staggering gait, with a tendency to fall forward or to one side. It is not always easy to differentiate between tumor and abscess of the brain. If the affection is accompanied by an inflammation of the middle ear, or by caries or necrosis of the cranial bones, the presumption is in favor of abscess. Intracranial hemorrhage with softening of the brain, as the result of thrombosis and embolism, may be distinguished from tumor by the fact that in these cases paralysis occurs suddenly without premonition, whereas in the case of tumor there are premonitory symptoms for a greater or lesser time preceding the attack. With the hemiplegia following cerebral hemorrhage or softening of the brain the cranial nerves of special sense are hardly ever involved. With hemiplegia caused by tumor they are always involved.

Meningeal hemorrhage is often accompanied by convulsions, and especially so if the cause is a traumatic one. It is rarely complicated by hemiplegia, and if the effusion is very great death may take place speedily. The diagnosis rests to a great extent on traumatism as a cause. It may occur as the result of aneurisms of the middle cerebral or basilar arteries and sometimes by a thrombosis of the cerebral sinuses.

Tetanus is a disease characterized by continuous rigidity of the muscles of the neck and jaw and a large part of the voluntary muscular system of the body, with paroxysms of tonic convulsions, the intellect remaining intact. Rigidity of the muscles is continuous and persistent, spasmodic contraction occurring at intervals. In some cases the muscular rigidity is so great that the body is rendered immovable. Stiffness of the muscles of the neck and jaw is one of the earliest symptoms. This is called trismus. During the most violent convulsive movements the body is thrown into various contortions, and opisthotonos and other conditions are developed. The paroxysms vary in duration and are accompanied by severe pain. This resembles very much the symptoms of poisoning by strychnine. In strychnine poisoning the symptoms develop suddenly. The convulsions come on immediately after the poison has been taken, and the first one is generally the most severe. In tetanus the symptoms come on slowly. There is rigidity of the muscles of the neck and jaw, and trismus is established. In strychnine poisoning the muscles of the lower extremity are first involved. There is complete relaxation of the muscles between the convulsions and the mouth can be opened. In tetanus there is never complete muscular relaxation and the jaw cannot be opened.

Treatment.—Diet is of great importance in the treatment of epilepsy. The pyloric sphincter of the stomach is often greatly relaxed and the food passes rapidly into the small intestines, which are also relaxed. This causes the ravenous appetite of epileptics, so that they "bolt" their food down without proper mastication. Animal food aggravates this condition and should not be taken. The patient should take at least three-quarters of an hour for each meal. If meat is allowed at all, it should be taken in the morning and never at night. The bromides of potassium and sodium owe their efficacy to the fact that they paralyze those peripheral irritations which cause the convulsions and other manifestations of epilepsy. Great care must be exercised in the use of the bromides, for these drugs can diminish the normal reflex excitability of the body. If given in excess they impoverish the blood, producing a tendency to extravasations, and cause an acne-like eruption on the face. The patient becomes sluggish in his movements and has loss of memory. They should always be given largely diluted with water and always after taking food. Cod-liver oil is a powerful adjuvant in the treatment of epilepsy. It offsets the injurious effects of the bromides and may be combined with small doses of phosphorus, about one-one-hundredth grain for each dose. If the acne is very severe, I have found Fowler's solution of arsenic in five-drop doses very effective. Very good results are often obtained by combining chloral with the bromides. Alcohol, in the form of whiskey or brandy, intensifies the action of the bromides and chloral. This is especially useful when the attacks are nocturnal. The compound spirit of ether, in drachm doses, is also very useful when the attacks are always nocturnal. If this line of treatment is carried out for a period of from eighteen months to two years, a cure will be obtained in many cases, especially of *le grand mal*. The manifestations of the *le*

petit mal are not so readily controlled. Epilepsy is sometimes due to an intracranial cause manifested by fibrillary twitching of the facial muscles during the night. Corrosive sublimate in one-twenty-fourth grain doses should be given three times per day. The convulsive attack, if taken in time, can often be prevented by producing some powerful impression on the surface of the body, such as the application of a hot iron or by a sharp blow. The excessive irritability of the skin can be overcome by the use of red pepper, to be applied in the following manner: To two pints of boiling water add two drachms of powdered capsicum. When it is cool moisten a sheet in the decoction, and wrap the patient up for half an hour, or until the skin becomes very red. This diminishes at once the excessive excitability of the surface nerves.

In the treatment of uræmic convulsions with dropsy, hydragogue cathartics are much more reliable than diuretics, for in many cases the kidneys will not act. I prefer the compound jalap powder for this purpose and usually give twenty grains for the first dose. Elaterium is also a very useful drug. It can be given in doses of one-eighth grain every two hours until four doses are taken. A very good diuretic pill contains one grain of calomel, one grain of squill, and one grain of digitalis. If the pulse becomes intermittent, leave out the digitalis. If symptoms are very urgent, the diuretics digitalis and the bitartrate of potassium may be tried. Their action is greatly hastened by the hot-air bath or by hot air introduced underneath the bed clothes. Pilocarpine in one-eighth grain doses seems to act well. If there is very extensive dropsy, numerous small punctures can be made with an ordinary needle, but not deep enough to draw blood. I have great faith in hypodermatic injections of morphine in uræmic convulsions. Bloodletting is a powerful means of putting off the immediate danger in uræmia, but it is applicable only in acute sthenic cases. It should never be done in chronic cases. For the prolonged treatment of chronic Bright's disease a pill containing one-twenty-fourth grain of corrosive sublimate, one grain of digitalis, and one grain of squill is very useful. When the pulse becomes intermittent the digitalis must be left out. Saturation of the system with the muriated tincture of iron, combined with small doses of corrosive sublimate, is also very useful.

Inhalations of chloroform are of the greatest value in the treatment of puerperal eclampsia. Bloodletting is indicated here, but, if for any reason, venesection cannot be performed, large doses of veratrum viride should be given. Begin with twenty minims of the tincture and when the convulsion recurs give twenty minims more. It may be necessary to give twenty minims every twenty minutes until its effect is produced on the pulse. It slows the pulse, makes the heart beat less strongly, and by opening up the arteries makes the pulse compressible. Chloral in combination with potassium bromide is very useful, ten grains of the former and thirty grains of the latter. Hypodermatic injections of morphine are also of great service.

Apoplexy is generally fatal. In these cases it is always advisable to give an active cathartic. One drop of croton oil placed upon the tongue is very effective. The question of venesection in apoplexy is an open one. If the patient shows symptoms of increased arterial tension with a red face, and strong carotid pulsation, and if the action of the heart is unusually strong, under these circumstances bloodletting is beneficial, otherwise it is not.

In the coma produced by opium poisoning, the stomach should be washed out at the very start, providing the patient is seen immediately after taking the drug. Twenty minims of the tincture of belladonna should be given every twenty minutes until the pupils begin to dilate, or corresponding doses of atropine sulphate may be given hypodermatically, beginning with one-fiftieth of a grain. Strong coffee should be given and every effort used to keep the patient awake. Artificial respiration may be necessary. The application of the faradic battery is a powerful means of stimulating the diaphragm and sustaining the heart. During the second stage, the patient should be laid down. Cardiac stimulants with large doses of brandy and water should be given; hypodermatic injections of one-one-hundredth grain of nitroglycerin at each dose; hot beef tea by the mouth or rectum every fifteen minutes. In the treatment of hysterical convulsions I believe in the prolonged application of the cold douche to the head. The patient should be held over a tub and ice-cold water poured continuously on her head until she begs for relief. This measure is most invariably successful in restoring consciousness. The administration of valerian, asafœtida, etc., is always indicated.

The treatment of tetanus is by no means satisfactory. Inhalations of chloroform are often useful: so is morphine in large doses. Potassium bromide is recommended also in large doses. Alcohol given to the extent of causing intoxication has been recommended. Ice applied to the spine is a useful measure. In strychnine poisoning tannic acid should be given if the patient is seen immediately after having taken the poison. This is to be quickly followed by an emetic. I have found potassium bromide and chloral in large doses very effective. As much as two hundred grains of potassium bromide and fifteen grains of chloral should be given for the first dose. Smaller doses can be repeated every twenty minutes. Artificial respiration and the administration of ether, chloroform, or amyl nitrite should be resorted to.

RETROGRADE CATHETERIZATION IN IMPERMEABLE DEEP URETHRAL STRICTURES, ILLUSTRATED WITH FOUR CASES.[1]

By A. F. JONAS, M.D.,

OMAHA, NEB.,

PROFESSOR OF SURGERY IN THE OMAHA MEDICAL COLLEGE; SURGEON TO THE OMAHA (METHODIST) HOSPITAL AND THE DOUGLAS COUNTY HOSPITAL, ETC.

Sometimes while doing an external urethrotomy for the relief of impermeable urethral stricture we may have the misfortune to lose all traces of the urethral lumen, and we may fail to find it after a prolonged and careful search. Even pressure above the pubes and in the rectum, for the purpose of forcing urine out of the central end, which often serves an excellent purpose in locating the proximal urethral end in the perineal wound, may fail.

Impermeable strictures may follow crushing perineal injuries which lacerate the deep urethra and more or less extensively destroy the peri-urethral structures, and in cases of gonorrhœal origin, complicated by urethral and peri-urethral suppurative processes.

When anatomical lines have become obliterated as the result of extensive cicatricial formation and we are unable to find our way into the bladder, it may become necessary to open that organ above the pubes, introduce a sound or catheter in the vesical end of the urethra down to the point of obstruction, and do retro-catheterization—in order that we may have a guide upon which to continue our incision and thus complete the waterway.

Common experience has shown that retro-catheter-

[1] Read before the Missouri Valley Medical Society at Council Bluffs, September, 1896.

ization in impermeable stricture is seldom required. The vast majority of deep and narrow urethral constrictions can be divided through the perineal wound. Therefore the experience, as will be detailed in this paper, is unusual.

The failure to follow the urethral canal into the bladder in these cases cannot be due entirely to inexperience, or to want of care and patience, for the reason that we had previously operated, entirely through the perineal wound, on seven cases of small-calibre strictures, several of which would not admit the smallest whalebone bougie. In the cases herein reported a resort was had to all the expedients usually employed for the purpose of finding and keeping in sight the urethra, and since a suprapubic cystotomy does not add materially to the gravity of the operation, and is easily and quickly done, we did not hesitate to resort to this method.

Case I.—H. R. D——, farmer, aged forty-three years. Has never had gonorrhœa or any other venereal disease. In February, 1884, while shovelling cobs from an ordinary wagon, he slipped and fell astride one side of the box. He was taken home, where he passed blood per urethram in large quantities for about half an hour. About one hour after his accident he drove three and a half miles to consult a physician, who attempted to pass a sound but failed. The patient was sent home and ordered to go to bed. He remained in bed seven days and in the house two weeks. Shortly after he drove a distance of nearly one hundred miles in a wagon, which greatly aggravated his affection, necessitating rest in bed for several days, his urine dribbling away. Since his injury he has always experienced difficult urination after hard labor or dissipation. Nocturnal enuresis has existed to a greater or less degree since his accident. He could always void his urine with greater ease while in a recumbent position. Frequent attempts at sounding have been made from time to time, but always without success. He entered the Omaha Deaconesses' Hospital, January 31, 1896. On examination we found him well nourished, and in every way he seemed in good health, except for his great difficulty in passing water, which he succeeded in doing only with the greatest effort and while lying on his side. The urethra seemed normal in the pars pendula, but no instrument could be made to pass the membranous urethra. After long-continued but unsuccessful effort with almost every form and size of instrument, external urethrotomy was decided on and agreed to by the patient.

On February 1, 1896, after the usual preparations and antiseptic precautions, the urethra was opened at the seat of stricture over the point of a sound, but no amount of search for the central urethral end was of any avail. A suprapubic cystotomy was then made, an elastic bougie was passed from the bladder into the urethra, and the operation was completed, as will be described more in detail in connection with another case. Recovery followed without complications, except for a suprapubic leakage.

He was discharged March 27, 1896, with the suprapubic wound closed and a fistulous opening in the perineum, which is now healed. He was able to pass a No. 25 French sound.

Case II.—E. E. M——, aged forty-one years, American, married. Occupation, stationary engineer. Entered the Omaha Deaconesses' Hospital, February 2, 1896. He was of slight build, poorly nourished, very feeble; was not able to be out of bed; suffering from urinary retention. He stated that nearly twenty years ago he was afflicted with a severe attack of gonorrhœa, from which he supposed himself to have recovered after several months' treatment. About ten years ago he observed that the urine was expelled less forcibly and in a smaller stream, since which time urination had become gradually more difficult, and during the last year his bladder had constantly been overdistended, with more or less dribbling. On examination three constrictions, 20 ch. calibre, were encountered in the pendulous urethra. But no amount of effort or patience would induce any instrument to pass into the pars prostatica. The collected urine exhibited elements indicating vesical catarrh. External urethrotomy was advised and consented to.

February 8, 1896, the urethra was opened by perineal section by the usual method. It was found to be impossible to enter the bladder by this route, on account of the dense cicatricial tissue. The bladder was opened above the pubes. An elastic bougie was guided by the index finger into the vesical end of the urethra to the seat of stricture. The operation was completed by cutting through the cicatricial tissue, so as to enable a sound to pass through the penile urethra into the bladder. Recovery was uneventful except for a slight suprapubic leakage, and that the perineal tube was displaced three times, giving considerable trouble each time before reintroduction was effected.

The patient was discharged March 7, 1896; able to introduce a 25 ch. sound, but was still suffering somewhat from vesical catarrh, which has now disappeared.

The following case will be reported more in detail, partly to illustrate the method of procedure, and partly on account of some unusual features connected with it:

Case III.—N. B. C——, married, aged forty-nine years. Occupation, lodge organizer. Entered the Omaha Deaconesses' Hospital, February 10, 1896. He appeared very anæmic, poorly nourished, weighing about one hundred and thirty-five pounds. He complained of an inability to pass his water, a condition which had existed for several years, gradually growing worse. He stated that twelve years ago he had suffered from vesical calculus, which was removed by litholapaxy. His urethra was badly lacerated during the operation. His urinary difficulty dated from that time. Hemorrhage, which was very copious at first, ceased at the end of the week, followed by purulent discharge lasting several weeks. He observed an increasing difficulty in urination. The stream, while at first not diminished in size, was not expelled with that force to which he had been accustomed. A year later the stream gradually diminished in size, so that in the course of four or five years micturition became difficult, painful, and at times impossible. He had undergone many catheterizations, sometimes very forcible, for the relief of retention, sometimes successful and sometimes not. He had submitted to many courses of sounding, electrolysis, secret solvents, and widely vaunted stricture dissolvents, with the result that now he had almost constant dribbling from the urethra, with a bladder distended almost to the umbilicus. He denied ever having had venereal disease. Although he was much enfeebled by long suffering and loss of sleep, no marked disturbance could be found in any organ except his urethra and bladder, and a moderately prolapsed rectum from constipation. On examination an obstruction was found in the prostatic urethra, which could not be passed with steel or elastic sounds or filiform bougies. The urine contained triple phosphates, epithelium, leucocytes, etc. An external urethrotomy was advised and was consented to by the patient.

Operation, February 12, 1896. Patient was placed under chloroform and in lithotomy position. After a careful surface and urethral disinfection, a steel sound was passed to the seat of obstruction. An incision was made in the median line, exposing the point of the sound. The wound margins were separated with retractors, and an attempt was made to follow the con-

stricted urethra into the bladder. The urethral calibre had become so small and tortuous, and the perurethral cicatricial tissue so abundant and dense, that all traces of the urethra were soon lost, and in spite of a very prolonged search could not be found. The abdomen and pubes were then disinfected and shaved, and then prepared in the usual way. The bladder was opened above the pubes and the wound edges were caught with silk guys and held apart. The index finger was introduced for the purpose of finding the urethral opening, but without success. With the aid of reflected light the bladder opening was easily found. An elastic No. 20 French bougie was easily passed to the seat of constriction. The perineal wound was again separated with retractors, the bougie point, which could easily be felt, was cut down upon, and the bougie withdrawn. Another attempt was made to find the constricted urethral lumen, but this again failed. The intervening cicatricial mass was excised to the extent of one-half inch from the bulbous portion. No attempt was made to suture the divided ends of the urethra. After a copious irrigation, the suprapubic wound was closed by three tiers of sutures, the first two with catgut and the superficial with silkworm gut. A small gauze drain was left in the lower angle of the wound. A collodion dressing was then applied. A rubber drainage tube, one-fourth of an inch in calibre, was introduced with one end reaching just within the bladder and the other end extending four or five inches outside the perineal wound, and joined to a second tube, which was of sufficient length to extend into a vessel partly filled with water under the bed. This tube, by its siphonage, kept the bladder empty, giving it physiological rest, draining away the urine as fast as it trickled from the ureters, depriving microorganic life of its nourishment, and in that way placing the bladder in the best possible condition for recovery. The space around the tube in the perineum was packed with iodoform gauze; over this was a large pad of absorbent cotton, then a perineal band. The patient was then placed in bed. The perineal dressings were changed daily. After the fifth day the bladder was irrigated through the perineal tube every day with boric-acid solution. The suprapubic dressing was removed in one week. The wound was found to be united, except at the point of drainage, where a small leakage was found, which persisted for several weeks and then closed.

March 27th, the perineal tube was removed permanently. On account of existence of local sensitiveness, the first sound, No. 25 F., was passed into the bladder under the influence of an anæsthetic. On the succeeding twelve days the patient was instructed in the passing of the sound, which he succeeded in doing very successfully. The perineal wound gradually closed. The patient was discharged April 9, 1896, with instructions frequently to sound his urethra.

Case IV.—T. Z. G——, aged sixty-two years, American, shoemaker, married. Admitted to the Omaha Deaconesses' Hospital, March 3, 1896. He said that about two years ago he fell astride of a fence, severely bruising his perineum, and especially his urethra. Immediately after the accident he suffered from prolonged urethral hemorrhage, painful and difficult micturition. After the cessation of the hemorrhage, swelling, and pain, urination was not free, and slowly but gradually became more impeded, until within the past three or four years it became very difficult, and at the time of his admittance he could void his urine only in drops and with the greatest effort. We found him fairly well nourished and otherwise in fair health. Pulse, 102; temperature, 99.5° F. Examination of the collected urine showed it to be milky in appearance with considerable odor, and microscopically it contained the elements indicating chronic vesical catarrh. An effort to enter the bladder through the urethra by means of bougies and sounds proved futile after repeated and prolonged attempts. The constriction existed in the posterior urethra. External urethrotomy was urged and agreed to.

Operation, March 5, 1896. A perineal incision was made down to the point of a sound which rested against the urethral obstruction. All efforts to trace the urethra through its bulbous and membranous portions failed. The bladder was then opened above the pubic margin, as in the preceding case. An elastic bougie, guided by the index finger, was introduced into the vesical end of the urethra, down to the point of obstruction. The perineal incision was then extended to the point of the bougie. A careful search for the urethra from within outward revealed a very small and tortuous canal, from which opened a blind pocket, probably the result of forced catheterization, and into which had passed the end of every instrument introduced into the urethra. The constricted portion was laid open. The same suprapubic suture, drainage, and dressing were used as in the preceding case; also the same perineal drainage and dressing. Recovery was uneventful, except for a suprapubic leakage which gave us much trouble, but ceased in about five weeks. His highest temperature was 101° F. On account of great restlessness the perineal drainage tube slipped out several times, and required an anæsthetic for its reintroduction. The perineal tube was removed permanently, April 5, 1896. He was instructed in the passage of the sound, and was discharged, April 24, 1896, able to pass a No. 24 F. sound. The perineal fistula was not entirely healed, but closed seven weeks later, as I was informed by letter.

External urethrotomy in impermeable deep urethral stricture, completed by the aid of suprapubic cystotomy and retrograde catheterization, is not a new operation, having been done by Verguin, of Toulouse as early as 1757. Fortunately the cases requiring such extensive operative procedure are not of frequent occurrence, particularly in recent times. With increased experience and better manipulative skill on the part of the surgeon, the vast majority of cases are managed so successfully that even simple external urethrotomy has become less frequent, and retrograde catheterization very rare. And for one surgeon to have four such cases in the same hospital at the same time is a very unique experience.

The method of procedure in our cases did not differ from the plans usually followed, except that for retrograde sounding an elastic bougie was used in place of the metallic sound so often recommended, on account of the danger of making a false passage with the metallic instrument, an accident which can occur while the sound is being pressed downward by the assistant in order that the point may be readily felt in the perineal wound. Again, we used a tube of large calibre and more unyielding walls in place of the soft-rubber catheter so often employed, on account of the freer drainage, the less liability of the tube to collapse, and the greater dilatation of the vesical sphincter, thereby more speedily relieving the spastic and irritated condition of the sphincter. The large free opening in the end of the tube gives freer exit to the tough tenacious mucus from the bas fond, keeping the bladder empty and giving it that physiological rest so important in the treatment of inflammatory conditions.

The most unpleasant feature in the management of these cases is the suprapubic leakage that is liable to occur in many of them. As soon as this occurs the siphonage through the perineal tube becomes imperfect, the tube is liable to clog, and frequent irrigations through the tube, in order to dislodge tenacious mucus and pus, become necessary. Frequent change of

dressing of the suprapubic wound is required. The integument of the lower abdomen becomes irritated and excoriations are liable to occur. The closest attention of a skilled nurse is almost indispensable. The wound as well as the surrounding skin must be frequently disinfected, covered with zinc-oxide ointment, and dressed with antiseptic hygroscopic dressings. These suprapubic fistulæ have, in my experience, all closed in a comparatively short time. The reason leakage so often occurs, even after the most accurate tier suture, is due to the infection from septic contents of the bladder, which exists in nearly every case. And until we shall have more perfect means for immediate disinfection of a catarrhal bladder we are liable to have this complication. The perineal fistulæ have given us more trouble. In several instances we have resorted to repeated currettings before closure was effected. In one case of simple perineal section for chronic vesical catarrh, without urethral stricture, the fistula existed nearly one year.

In Case III. we extirpated the entire cicatricial mass involved in the stricture without any attempt to coaptate the resected urethral ends. When we consider for a moment that it is impossible to maintain an aseptic condition of the urethra under ordinary circumstances, and certainly less so in diseased conditions, we know that any attempt at suturing, or transplantation of mucous membrane must be a failure. The sutures become infected and cut through the tissues. Repair must be by granulation and cicatricial contraction.

The remaining cases were not treated so on account of our having had no personal experience with this method. But I am convinced from further reflection, as well as by a study of the pathology and a consultation of current literature, that the proper procedure in every case is to extirpate all of the cicatricial tissue involved in the stricture.

We have practically a fibrous cord extending from the distal to the proximal urethra. This cord has lost all the elements of a urethra. No matter how carefully we split along its narrow and tortuous calibre, all attempts to transform the resultant groove into a urethral wall will fail, because it is denuded of its epithelium and subepithelial tissues, which are so necessary to its elasticity.

In our soundings, however carefully done, this cicatricial cord is pushed to one side, the defect heals by granulation, and we have again a long cicatricial tube. If we excise the strictured urethra, the granulation process proceeds to its ultimate cicatricial formation, and contraction takes place, we find that the resected ends of the urethra are drawn toward each other, resulting in a thin, short annular cicatrix, which in time and with proper care will almost entirely disappear; while in the other case the remaining thick cicatricial structures interfere with gradual approximation of the unaffected urethral ends, making the results unsatisfactory.

The question arises, how much of the urethra can be safely exsected? Eugene Fuller[1] reports two cases, in one of which he removed the "entire bulbous urethra, and an inch of the penile urethra anterior to the bulb, and the anterior half-inch of the membranous urethra," with success.

In all of our cases no instrument was placed in the anterior urethra, and no attempt at sounding was made until the perineal drainage tube was permanently removed, the tube being retained until the urine had become clear and free, or nearly so, of epithelium, triple phosphates, leucocytes, etc. Then a sound was passed into the bladder and retained for from five to ten minutes, and replaced daily with increasing sizes, until the full capacity of the urethra was attained. The patients were always instructed to do this themselves, and on leaving the hospital were provided with a proper sound and warned to continue sounding for a month every day, after a month each alternate day for two months, then making the time between the soundings longer, but to sound at least once a week for a period of two years, with the warning that all urethral strictures are liable to recur unless prevented by the regular passage of the largest possible instrument.

CRANIAL SURGERY.[1]

By F. W. HIGGINS, M.D.,

CORTLAND, N. Y.

UNTIL the last decade or two the cranium has been the *noli me tangere* of surgery. Some time after the peritoneal cavity had ceased to affright the surgeon, the head remained a dark continent. The reasons for this are not far to seek.

Among these are the difficulty of making an opening into the cavity through the cranium, the shock of the operation, the profuse hemorrhage from the scalp, the small field of operation, and limited opportunity for observation after the opening is made—all in marked contrast to the abdomen, where the whole hand can be introduced, if necessary, to aid in the diagnosis; then there were the erysipelas, pyæmia, and septicæmia which in the pre-antiseptic days of surgery seemed more likely to follow head injuries than any other class. Even after the advent of antiseptics and aseptics the difficulty of carrying out the technique on the scalp seemed for a long time insuperable. Added to all these was the apparently insurmountable impossibility of making a correct diagnosis of an intracranial affection before operation or of localizing it, so that we can easily understand why cranial surgery was last to be developed.

Already to some extent have these barriers to brain surgery been overcome. With a conical thin-edged trephine an opening can be quickly and safely made through the bone. If a larger opening is necessary, a semicircular bone flap can be raised which can afterward be replaced.

We have learned how to manage hemorrhage with hæmostatic clamps during the operation. If he is supplied with a couple of dozen of these the bleeding does not delay the surgeon at all, and all necessity for resorting to the difficult process of ligaturing is dispensed with. Hemorrhage from a cerebral sinus, which sometimes pours out in such a torrent, is, after all, only venous, and is found to be easily controlled by pressure of a tampon of gauze.

Antisepsis cannot be used at all when the delicate structures of the brain are exposed. But recently asepsis is the motto of surgery, not antisepsis. All the instruments used are sterilized by boiling alone, and are then kept on a sterile towel. The head itself is shaved the day before the operation and scrubbed for an hour with green soap, then with ether, and then with a brush and bichloride. A cap wet with bichloride, 1 to 2,000, is then applied and worn over night, to be removed only at the table, where a last scrubbing is given.

To the diagnosis and localization, in which such great strides have been made in the last few years, I can only briefly allude, after I have given a report of a case operated on at the hospital, August 27th.

C. B——, aged twenty-three, a farmer, a well-built healthy young man, was thrown from a wagon, July 18, 1895. He struck his head upon some stones, causing a scalp wound just to the left of the median line near the vertex. No injury to the skull was apparent, and he

[1] Read before the Cortland County Medical Society, December 10, 1896.

went to work three days after it was dressed. In the afternoon of that day he had an epileptiform attack. He did not lose consciousness, but there were tonic and clonic convulsions. After that he complained of a constant heavy feeling in the head, and every month or two occurred an attack somewhat similar to the first one. During the month before I saw him he had two, the last being much more severe than any which had preceded. In this one he became unconscious. The description given by his wife of this atttack on August 19th is that he was sitting quietly by the stove, when he suddenly jumped and grabbed the stove-cover lifter and began to strike aimlessly with it; then he scattered the dishes from the table about the room, and threw over a chair; he then began to toss his arms about, to throw himself against the wall and then to roll on the floor; then he was seized by cramp. As she tried to give him something from a teacup he bit a piece out of the side of it. These performances continued about a quarter of an hour, and were followed by a stupor of an equal duration. After this he had cramp again, but became unconscious at six o'clock, about three hours from the beginning of the strange actions.

The examination of the patient did not reveal much more than the history had done. The optic nerve looked hazy, what is called woolly, but it could not properly be called choked disc. On measuring the distance from the inion to the glabella it was found to be just twelve inches. The posterior end of the scar was situated just half an inch in front of the point midway between the two; as the upper end of the fissure of Rolando is half an inch behind this point, the scar would evidently lie in the anterior border of the motor area. It was thought that while the symptoms were rather indefinite, still from the fact that they came on three days after the injury, and consisted of motor spasms due to some cortical irritation, an exploratory operation would be justifiable. The nature of it was fully explained to members of the family, who willingly consented to it, taking all the risks of non-success and of danger. Indeed, they were anxious to have it done, since all treatment had failed to control the attacks.

The aseptic precautions already detailed were carried out in every particular. Care was taken to locate the ends of the scar on the bone by a drill before the incision was made. The flap from the scalp was made horseshoe form, with the base down for its better nourishment. The first button of bone required some little time for its removal, since the skull proved to be very thick and necessitated frequently stopping and testing the groove in order to avoid the danger of injury to the cranial contents. The buttons were taken away, and the chisel was then used until a triangular opening with smooth sides was produced. Beyond the excessive thickening of bone nothing abnormal appeared. The dura was carefully opened, but, the inside of that looking healthy, no further search was made. Since the operation was done for the relief of pressure and irritation symptoms, the bone was not replaced, but the flap was sutured carefully in place. Recovery was entirely uneventful. At the first dressing one week later union was almost complete, and the stitches were removed. One week later the patient left the hospital.

Of course it is yet too soon to know what permanent benefit the patient will derive from what was done. During these four months, however, he has had no attack, and his head feels much clearer and better, and he is able to work, with nothing to show for his experience except a soft spot on the top of his head.

In another case in which I operated about a year ago for sarcoma of the parietal bone, that of a patient of Dr. White, the localization symptoms were much more definite than in the one just given, and very interesting. The first irritation symptom was an epileptic spasm before admission to the hospital. He was relieved by the removal of the growth, until it began to recur inside the dura mater, when one-sided spasm and one-sided paralyses began to appear which corresponded exactly to the motor centres about the fissure of Rolando that were diseased.

It is the mapping out of these motor centres during recent years that has given such an impetus to cerebral and cranial surgery. This is so important a subject, and at the same time so difficult to carry clearly in mind, that I make no apology for referring to the salient features of the cortical motor areas. I am aware that they are probably not unknown to any of my readers, but a short review of them can, I am sure, do us no harm.

The fissure of Rolando, about which cluster the most important cortical motor centres, is also called the central fissure. The simplest way to locate the upper end is to find the middle point between the glabella—that is, the point between the eyebrows above the root of the nose—and the inion, or the occipital protuberance. One-half inch behind this point is one end of the fissure. From here it extends downward and forward at an angle of 67½°. This angle, it will be noticed, is half-way between 45 and 90°. The length of it is three and three-eighths inches, which can be closely estimated upon the forefinger.

Around the lower end of this fissure clustre the face centres, at the middle the arm centres, at the upper end those of the lower extremities. Just in front of the face centre is the co-ordinating centre for speech, and just behind the arm centre is that for handwriting. While these centres can be more or less exactly separated into minor ones, these general landmarks alone will enable one to arrive at quite definite conclusions, always remembering that the lesion is on the opposite side from that of the paralysis or spasm. Paralysis, of course, may arise from a blood clot or solution of continuity in the basal ganglia, or subcortically anywhere along the tract of the nerve connections. But when spasm occurs, either alone or in connection with paresis, it is pathognomonic of a cortical lesion.

Choked disc, which can be so easily determined by the ophthalmoscope, is a very certain indication of some intracranial growth or localized inflammation. Its value in locating the tumor or abscess is, however, almost *nil*. To be sure, one may say, in a general way, that the symptom is almost always present in growths of the cerebellum, and is not so common in those of the cerebral cortex, but so many exceptions occur that the most one can say from the presence of papillitis alone is that there is probably present somewhere in the brain some new formation. Its connection with these growths is so frequent that in perhaps ninety per cent. of such cases choked disc may be found in some period of their history.

There are many other interesting eye symptoms which may assist in the effort to locate an intracranial lesion. Hemianopsia is present in many cases of basal lesion. In its usual homonymous form it indicates some affection of the optic tract behind the commissure. This may be in the optic tract itself, in the optic thalamus, or nearer the cortical centre, which we know to be in the occipital lobe. Paralysis of any of the ocular muscles may occur. The one most subject to attack is the external rectus supplied by the sixth nerve. This is due to its long course forward from its apparent origin at the posterior border of the pons. The cerebral centre for the oculomotor nerves has not been fully worked out, but is supposed to be somewhere in the parietal lobe. It is very difficult to explain the combination of paralysis and spasm present in cerebral apoplexies when we get

the eyes turned, as we generally do. But one empirical rule may be remembered that is very generally true. The eyes are turned to look toward the side on which the lesion occurred.

The variations in the size of the pupil are also to be noticed as assisting in localization.

Those cortical centres which have been most carefully mapped out are, perhaps, those whose disease produces the manifold forms of aphasia. At least five different centres are here concerned, situated in as many different parts of the cerebrum. The cortical centre for the auditory nerve, for instance, is situated in the temporal lobe, just above the ear. Total destruction of this centre would, of course, produce total deafness; but only such a part may be pressed upon that the condition of soul deafness arises. Noises and words are heard perfectly, but a word conveys to the mind no idea. The name of a thing is heard as a noise, but calls up no image of the thing itself. If you ask such a patient a question, you might as well have spoken in Choctaw as far as conveying any idea to his mind is concerned. Such a person may even retain his ability to speak, but can carry on no conversation with his friends, because the answers received mean nothing to him.

If, however, in such a person the occipital lobes should remain intact, communication with him may be opened up by means of writing. Written words convey a meaning to him, and he may answer a written question by the voice. Or the ability to write may be destroyed by an accident to that part of the cortex just behind the middle of the fissure of Rolando. Or that may occur which is perhaps most common—the ability to pronounce words may be wholly or partially lost, or the entire loss may be only partly recovered from. This centre is situated between the long and short arm of the fissure of Sylvius.

Not only may the centres themselves become diseased or injured, but the complicated system of nerve fibrillæ which binds them together, enabling them to work in harmony, may be disturbed in some part. If this should occur, for instance, to the fibres uniting the hearing centre to the motor centre for speech, while the centres themselves remained intact, then the patient could understand the spoken words or could express himself, but to repeat words that he had just heard would be impossible. The path between the point where the word is recognized and that where it is reproduced is destroyed. It is also very easy to see how impossible it is for all these complicated associations to be reformed in the right side of the brain if they are destroyed on the left after adult life has been attained.

The last speech centre to be mentioned is the most important of all. It is known as Broca's centre, situated in the inferior frontal convolution on the left side. Here the idea of speech seems to be located, however it may be expressed. Here the thought is clothed in words, and disturbance here is irremediable.

By the aid of the other symptoms which might be spoken of, such as the crossed paralysis originating in the pons, the vertigo from affection to the cerebellum, the mental hebetude and slow pulse that accompanies many cerebral growths, and so on, it will be acknowledged that the diagnosis and localization of intracranial lesions are becoming as certain as those of lesions in any other locality, although requiring, possibly, a little more time for study. It is from a consideration of these recent advances that we must admit that there is hope for cranial surgery, and that it has already a legitimate field.

Tincture of Aloes is suggested as an application to varicose ulcers.

CROOKES TUBES AND STATIC MACHINES.

By S. H. MONELL, M.D.,

BROOKLYN, N. Y.,

CHIEF INSTRUCTOR OF THE BROOKLYN POST-GRADUATE SCHOOL OF CLINICAL ELECTRO-THERAPEUTICS AND ROENTGEN PHOTOGRAPHY; FELLOW OF NEW YORK ACADEMY OF MEDICINE, KINGS COUNTY MEDICAL SOCIETY, ETC.

The Medical Record of November 28th reports the use of *x*-rays in detecting thoracic aneurism, and states, as evidence of the power of a Crookes tube: "The speaker had put a healthy young man, wearing all his clothes but his coat, between a tube of special construction and the fluoroscopic screen, and in twenty seconds he could clearly see not only the ribs, but the heart pulsating, and the latter was so distinct that it was possible to tell the ventricles from the auricles." Probably no physician who has read this paragraph has failed to recognize the possible value of such an aid to diagnosis, or to wish to procure an equally efficient tube for himself. There yet exists, however, great diversity in Crookes tubes. No standard size, shape, or degree of vacuum can be determined unless a standard current also has been decided upon. Each means of electrical excitation demands a different adaptation to itself of the size and shape of the tube, the size and relation of the electrodes, and the degree of vacuum. This has led to much misunderstanding, to many conflicting and unfounded statements by different writers, and to many disappointments on the part of buyers of tubes, suited, perhaps, to other methods of excitation, but ineffective in their own hands. In the paper on Roentgen's discovery which I read before the Kings County Medical Society on April 21st of this year, I then said: "A powerful static machine with Leyden jars and transformer coils will do fairly good work, but far from the best."

This opinion was shared by all the leading workers in the field at that time. It was based upon the tubes then made, but it is no longer true. Until June my own observation and experience continued to confirm my belief in the superiority of the coil apparatus I described in April. During the past four months, however, I have made a large number of experiments to determine the actual facts in regard to tubes and exciting apparatus for physicians' use, so that the physician who has a choice between therapeutic and non-therapeutic electrical apparatus may employ the one that will serve him best and profitably.

There is a general confusion of ideas among makers as to what constitutes a "high efficiency tube." Some are satisfied with a display of the bones of the hand. Very few makers or expert operators really know the full capabilities of a superb tube, for few have seen them developed. Common tubes of ordinary vacuum are now plentiful. They will glow with coils giving from two to six inch sparks, and gratify the wayfaring man, who is amazed to see his own bones; or they will produce negatives of even the trunk of the body in the course of time. These ordinary effects are of but insignificant value in diagnosis. Tubes suited to larger coils, giving ten to twelve inch sparks, may also easily be obtained. Double-focus tubes and alternating currents are also available, and are often regarded as exceptionally efficient. When these tubes are purchased by physicians who have static machines and have read that they can be used to produce *x*-ray effects, the result is almost invariably disappointing.

To explain why this is so, and to enable medical users of Crookes tubes to employ their own apparatus successfully, are the objects of this paper.

When the bulb of a tube is of a proper convexity, it will throw rays upon a screen held at many feet—ten or even twenty—from the tube itself. Such a rounded convexity is required to make fluoroscopic examinations through thick bodies, for if the bulb is acutely

oval the rays will quickly converge and the maximum of efficiency fades at once within a very few inches of the tube. If the internal electrodes are too far apart or too near together, they impair the effect. The space between them best suited to the large Holtz machine is three inches, with a margin of one-half inch either way, according to the size of the tube. Very small or large tubes are unsuited to static machines, as a rule, although the construction and vacuum may be so well adapted to this current as to make exceptions of special tubes. Medium sizes have been the best that I have seen.

When the external terminals of a tube are connected directly to the prime conductors of a Holtz machine, we have an immediate and infallible test of the vacuum. What the correct vacuum should be cannot be stated in terms of fractions of an atmosphere, but the demonstration of its degree is as absolute as mathematics. If it is a very low vacuum, the electrical discharge will pass in a bluish stream between the electrodes, and no luminosity will glow in the tube. If it is a little higher vacuum, the visible blue stream will disappear, and in proportion as the vacuum rises the green glow will increase in brightness. At the same time the spark stream between the prime conductors is also indicating the vacuum to be very low, or some degree between very low and very high.

A current will pass through conductors in the direction of least resistance. If the vacuum is low its resistance may be so small that it may equal only a small fraction of an inch of air gap. A vacuum so high that a six-inch spark coil will send nothing through it, may demonstrate no more than a one-half-inch spark stream between static poles. A suitably high vacuum should force back by its resistance at least one and one-half to two inches of spark stream. The green glow in the tube will then be exceedingly bright, and *x*-rays can be developed of very high efficiency. No tube that does not furnish this demonstration is adapted to large static machines, and if physicians will ascertain the facts before buying tubes they can avoid both disappointment and expense.

The outer terminals of a proper static tube must be ten inches or more apart, and attachment to machine should be made with insulated wire of about No. 18 in size, as the fine wires so often employed sway too readily and leak off the current when the attraction of opposite polarities brings them near together.

I have kept a written history of the behavior of twenty-six tubes, tested in recent months, in my office. A tube of lower vacuum than it should possess for convective discharge excitation, will produce efficient *x*-rays when the oscillating static current is used with small Leyden jars. The maximum of steadiness and radiance can be found by short-circuiting the poles and then gradually drawing them several inches apart until the best effect is developed. The plates of the machine should revolve as rapidly as is consistent with safety. This method is open to objections. It is noisy and the oscillations try the eyes. It sets up some heat in the tube, but very little as compared with the street current. The convective method is preferable. When the vacuum is just right the terminals may be attached directly to the prime conductors of the static machine, without employing any jars, coil, or other device. Revolve the plates rapidly, and on drawing the poles apart the tube will instantly light up with the brilliant green phosphorescence so familiar now to all.

If the electrodes are in proper relation all the current will be focussed upon the anode, and the bulb will appear in twin diagonal hemispheres—one in eclipse and the other luminous as the sheen of a strong light. If, now, the hand is examined through the fluoroscope, the bones that were merely a black shadow with a tube of low efficiency will be nearly as white and transparent as the soft parts. The beautiful mechanism of the wrist-joint will appear in clear detail. A group of metallic objects on the back of a pine board will show through a book of sixteen hundred pages, or a heavy brass tray, such as I use for a foot plate with my static machine. When a tube does this, I know it is a good tube. By further arts of management, such as all tubes require, efficiency can be still further developed, and demonstrate the ribs, the spinal vertebræ, the movements of the heart, and all other effects so far attained by any operator with any means.

The tube does not overheat, and there is no apparent tax upon it or limit to the time it may be run at full power. It does not break down under strain, and it cannot be overloaded. The convective current makes no noise. The glow of the tube is as steadfast and unwavering as moonlight in an unclouded sky.

This economy in the durability of tubes is a factor of great importance beyond the first cost of the tube, for a tube that has proven its high worth and exceptional capacity is priceless. Money alone will not replace it if it is injured or broken. Moreover, none of the alleged injurious effects of *x*-rays, reported hastily and with more or less sensation, are caused by the static current. It seems wellnigh impossible that alopecia and dermatitis should be attributed to *x*-rays by practical medical observers; but as they have been so attributed and no one has, to my knowledge, pointed out the error of this view, the simple fact may here be stated that these electrical or heat effects, which resemble sunburn, result from the action of heavy currents operating large coils and are not due to *x*-rays. Roentgen's classical report contained the statement, "The rays have no calorific effects;" and I am not aware that any one has yet shown Roentgen to be mistaken.

The advantages of safety, facility, life of tube, comfort in operating, absence of heat effects, and stability of the radiance are among those afforded the physician by the static machine. The questions of cost and availability are also to be considered. When no tube was made that would operate well with the static machine, the coil was obligatory; but the large coil outfit cannot be used by the physician in medical practice and is a useless luxury when not producing *x*-rays. The superior value of an office or hospital equipment, costing no more than an approximately effective coil outfit and capable of a wide range of therapeutic uses, is self-evident. Such an equipment is to be found in the improved Holtz machines now made. This type of electrical apparatus can be operated by the surgeon, or general practitioner, or specialist far more readily than can galvanic or faradic batteries in their therapeutic work. Instruction in its management can as readily be procured as instruction in the use of any medical or surgical apparatus. But its double advantage of value to the physician in two fields instead of the single utility possessed by the Ruhmkorff or Tesla coil would not suffice to displace the coil if the latter was much the most effective in *x*-ray work. The time is nearly at hand when leading hospitals and physicians throughout the country will be deemed behind the age if they are not prepared to employ this aid to diagnosis. It is therefore important to point out the satisfactory fact that electro-therapeutic and the maximum of *x*-ray efficiency are obtainable with the same apparatus—to wit, the static machine. I am aware that nearly all the weight of authoritative utterance up to this date is against this conclusion. Nevertheless, I have never failed to demonstrate its accuracy since I have been able to procure tubes made partly after my own suggestions and adapted to the static apparatus. The whole matter lies in adapting the tube to

the apparatus, and not the apparatus to the tube. When this is successfully done the demonstration of superior efficiency is complete.

I recently showed certain effects to an expert maker of Crookes tubes, and asked him what a coil would cost which would produce equal effects. His reply was emphatic that "no such coil could be bought at any price, not even for a thousand dollars." On another occasion another leading maker stood in open-eyed astonishment before a tube in my office, which was excited by my eight-plate thirty-inch Holtz machine. The plates were run at high speed by an electric motor, and the screen glowed as if striving to burst into incandescent light. He had seen the best effects produced in the laboratories of distinguished electricians, and he was an accurate judge of progressive advances in this field. He not only came to my office predisposed in favor of coils, but had been informed by world-renowned authorities that the static machine would break tubes and was inferior to the poorest coil. Without a word of argument on my part, he gazed at the to him marvellous radiance so easily and instantly produced in his own tube, which his own coil would not excite at all, and made the following remark in a deliberately impressive manner: "I now see that the best way to excite a Crookes tube is with the static machine. No coil will equal it."

It is my belief that with a special static tube I can demonstrate the truth of this conclusion to every competent observer. I have never broken a single tube in any of my experimental work with this apparatus, although I have at various times employed in tests between forty and fifty tubes of different makes and construction. I have never discovered any of the injurious heat effects reported by those using street currents of large amperage, and my tubes operate for hours at about blood temperature. Some experimenters early abandoned the static machine in *x*-ray work and turned again to the coil; others have seen demonstrations of all methods by some of the best experts in this country, and have relegated the static current to second or third place. There are several hundred physicians to-day who would eagerly employ Roentgen's wonderful discovery by the aid of apparatus they already possess, if they were aware that it could be done. To a hospital the advantage of utilizing a therapeutic machine already among the essentials of its equipments is manifest, for few hospitals can afford additional and costly luxuries for diagnosis alone. Moreover, any coil or tube which will do less than show the heart beat, or fail to produce a good negative of the trunk of the body of an adult with an exposure of five minutes, does not possess the high efficiency the medical man requires.

But three things are needed to place this degree of efficiency in the hands of all who desire:

1. A Holtz machine of the therapeutic type and size, operated by a motor.

2. A Crookes tube specially adapted to this form of high potential current.

3. A practical knowledge of technique.

I am sure that this will be welcome information to many physicians who hesitate at the extra expense of a good coil. Of the accuracy of the statements here made I have had the most convincing proof during a sufficient period to remove the uncertainties of hasty judgment. I have demonstrated the facts both to physicians attending my clinic and to manufacturers who have been previously sceptical. I am prepared to maintain: 1st. That no method now known, however costly, will surpass the efficiency of the Holtz machine with tubes suited to it. 2d. That the Holtz machine and tubes adapted to its maximum discharge will readily and economically equal or surpass the best *x*-ray effects producible by any or all other means of electrical excitation with any design of tubes that can now be obtained. In the interest of medical and surgical institutions and practitioners desiring to utilize *x*-rays, these facts should be made known.

865 Union Street.

THE TREATMENT OF GOUT.

By CHARLES C. RANSOM, M.D.,

visiting physician to charity hospital, new york.

In considering the treatment of gout, I shall confine myself to the methods of treatment, both medical and hygienic, which I have found to be of the greatest value in my own experience: and while in certain instances I may refer to those employed by other practitioners, but which I have not myself used, it will be simply to point out several methods of procedure which I believe may be of equal value. I do not wish to be understood as originating any special method or as making claims of superiority of treatment, but during the past ten years I have had the opportunity of seeing and treating a very much larger number of cases of gout than often falls to the lot of the general practitioner, and I have had during that time ample opportunity of trying many methods. I may be pardoned, then, for giving you briefly the result of my personal observations.

In order to facilitate the study of the subject, I shall consider the treatment under three heads, in the following order: 1. The treatment of the gouty diathesis. 2. The treatment of chronic gout. 3. The treatment of acute gout.

As will be readily understood, it is not possible to divide the subject in practice arbitrarily as I have done here, as many of the manifestations of the gouty diathesis may rightfully be considered phases of chronic gout, and exacerbations of chronic gout and an acute attack developing *de novo* are practically the same, so far as their treatment is concerned. For our purposes here, such a classification will undoubtedly aid us.

The Treatment of the Gouty Diathesis.—The treatment of the gouty diathesis may be subdivided into medicinal treatment and hygienic treatment. The use of drugs other than tonics and digestives in cases which are undoubtedly gouty, but in which none of the special manifestations of the disease exist, are of doubtful efficacy; in all these cases, however, the general condition of the system is, as a rule, below par, and there is always more or less anæmia.

In order to restore the general tone and to increase the standard of the red blood corpuscles, some form of iron, with or without the addition of arsenic and strychnine, is of undoubted service. In elderly subjects in whom the muscular system is markedly under tone, the addition of digitalis in small doses will be found of great value, not only through its specific effect upon the weakened heart muscle, but as an aid to the digestive power through the stimulation to the visceral circulation. The use of alkalies in large doses has never been of great value in my hands, and when used at all they must be used only in the robust. I know that many observers set great store by the use of these agents, and no less an authority than Burney Yeo maintains the efficacy of the alkaline treatment, in support of which he says:

"In spite of all the theoretical denunciation of the use of the sodium salts in gout, the gouty from all parts of the world flock to those very continental springs in which these salts are most predominant."

While it is true, as Yeo says, that many gouty people visit those springs and undoubtedly derive great benefit from the use of the waters, the value of them, to my mind, lies not in the alkali which they contain, but in the large amount of water which the patients drink in order to get the alkali. This is also true of the

various lithia waters, and, in fact, of very many waters which are on the market. I have very little faith in the value of lithia, whether in a natural water or in tablet form. I frequently prescribe lithia tablets, however, but for quite another reason. I find if I order six glasses of water to be taken at stated intervals during the day, I rarely find a patient who will conscientiously take it in full amounts; if, however, I order six lithia tablets to be taken, each dissolved in a glass of water, I have no difficulty whatsoever—in fact, the seventh may be asked for.

You may deduce from the foregoing that I believe in the ingestion of large quantities of water, which is indeed true. It is sometimes of advantage to prescribe some of the water hot. This is particularly the case with those who suffer much from indigestion. In those cases, if three of the six glasses are taken hot, one before each meal, not less than an hour before, the stomach is thereby better prepared for the meal which is to follow, and in many instances the discomfort after eating is quite removed. For the irregular action of the bowels which is of so frequent occurrence in the gouty, some one of the hepatic stimulants will be found of great service. If the movements are loose, I am in the habit of giving calomel in small doses, for a day or two at a time, then withholding it; if constipation exists, small doses of calomel at night, followed by the sulphate of sodium in the morning, or it may be taken alone in smaller amounts dissolved in the hot water which precedes each meal. A very excellent preparation for a more active laxative in the gouty is a pill containing colchicum, colocynth, and calomel. One of these pills may be taken at bedtime: care must be exercised in their use, however, as it is not desirable to produce too free catharsis. While most authors speak of baths as a good remedial measure, many have little faith in their efficacy, I judge, from the faint praise accorded them; and this comes, I am sure, from either lack of experience with them or carelessness as to the detail of the bath procedure.

Medicated baths are of estimable service in the treatment of the gouty diathesis, and in fact I may say I believe the bath treatment properly conducted to be by far the most important method at our command for ridding our patients of this condition.

Medicated baths are of two general kinds—the artificial or prepared bath, and baths of the naturally mineralized waters. As to the comparative value of these baths, those consisting of the natural waters are in every way vastly superior. There is an element of virtue in the natural combination of the mineral water, which we are unable to obtain in combining the same chemical agents in an artificial bath. To this unknown element much of the efficacy of the medicated bath is due. No less an authority than Trousseau said of this influence: "Whatever may be said of them, mineral waters are not simple medicaments; whatever may be the predominant mineralizing agent as demonstrated by analysis, it acts not alone. Nature, in combining with the more or less notable elements which chemistry may isolate, other exceedingly variable ingredients which have not yet been discovered, has done for this mineralized agent that which we seek to imitate each day in our prescriptions, when we endeavor to reinforce or diminish the effect of a medicinal substance by associating others with it. Much pains is necessary, however, in the detail of applying the bath, not only to enable us to obtain desirable results, but to avoid doing harm; for injudicious bathing is productive of serious ills."

In this connection must be borne in mind the fact that results may be obtained from the hydrotherapic standpoint alone, irrespective of the mineral ingredients contained in the water. This may be seen in the tub bath, in the different effects produced by baths of different temperatures and of different duration; and in the douche, by the differences in temperature, duration, and force of impact of the stream used. As my experience with mineral baths has been especially in the use of sulphur waters, I naturally feel that this class of waters is unsurpassed in the treatment of the gouty diathesis, and I may be justified in my opinion by the most excellent results which I have obtained from their use—results which have not been surpassed at any springs, so far as I can learn. The form of bath which we are in the habit of using in this class of cases at Richfield, and which seems to answer the purpose best, is the immersion or tub bath. The dose of the bath, if I may be permitted the expression, is regulated by its temperature and duration. The temperature and duration will be found to vary with different subjects, from 96° to 108° F. for the former, and from five to fifteen minutes for the latter. The object sought in the application of the bath is to give such a bath as will produce to the fullest extent the physiological effect without exceeding it, for then depression will be sure to follow and harm may result.

In determining the proper dosage, much care must be exercised, for different patients vary very much in their reaction to the bath; and it will also be observed that the same individual will vary at different times.

A large experience, then, is necessary properly to conduct the bathing procedure, and careful and frequent observation of the patient must be had. We usually begin with a bath at a temperature of 98° F. and duration of eight minutes, followed by complete rest of an hour in bed. This bath is taken three days in succession and preferably in the forenoon, two and one-half hours after a light breakfast. After the third bath the patient reports, and we note carefully the effect of the bath, as seen by the sensations of the patient during and immediately after the bath—whether or not there is depression or fatigue, whether there is exhilaration, how long these sensations last after the bath, if after the rest in bed following the bath there is any fatigue or depression, if there is sensation of fulness in the head or oppression of breathing during the bath, excessive perspiration following the bath, etc.

From these subjective symptoms and careful physical examination of the patient we determine whether it is wise to increase or diminish the dosage or to continue it as we have begun. These observations must be made every three or four days throughout the entire course of treatment, in order to insure the best results.

It is the custom with some physicians, in all cases in which the baths are found to be depressing, to order the bath every second or third day instead of modifying it. To my mind this is very bad practice. If a bath is so depressing that a patient can take it only once in three days without ill effects following, it is never a proper bath for that patient. The bath should be modified by lowering the temperature and shortening its duration, and it is exceedingly rare that a bath cannot be properly adapted by these means. A bath at 96° F. for five minutes or even less will often accomplish everything desired, although to some it may hardly seem to be worth the while.

It will be found that nearly all patients taking a course of baths will suffer from a general systemic disturbance, usually within the first week. The symptoms manifested in this condition are those of general malaise, headache, anorexia, with coated tongue and either constipation or a slight diarrhœa.

This is the condition described by writers on balneology as the "bath fever," and shows to the most sceptical that the medicinal bath is not a simple washing process, but is capable of producing as marked systemic effects as the ingestion of a drug.

At this time I omit the bath for a day or two; this, together with the administration of a little calomel,

always suffices to correct the condition. From this time on, during the course of baths, it is rarely necessary again to interrupt the bath. The course of baths usually consists of twenty-one, but this number is purely arbitrary and frequently it is desirable to give more, though less than twenty-one is not enough to produce good results.

Exercise.—Next to the bath, regular and systematic exercise is of great importance in this condition. When it is possible, active exercise out-of-doors in gradual and increasing amount is to be ordered. The various forms in which exercise may be taken is a matter of choice with the individual, but let it be borne in mind that if, for instance, walking is the form chosen, a short, brisk walk of even five minutes is of far more value than a half-hour's slow and indifferent stroll. In conjunction with active exercise or without it, in those cases in which active exercise would entail too much fatigue, may be ordered passive exercise in the form of massage or Swedish movements.

Massage, to be of any value, must be properly and scientifically done. There are many people who pose as masseurs and masseuses who do not know the first thing about the subject, and these people must be avoided if one would not do his patient harm.

Diet.—In the matter of diet, various opinions are held by different writers upon the subject, but it is not the province of this paper to discuss the merits or demerits of any special plan or the reason for adopting it, but to give you briefly an outline of the diet which has answered best in my hands. It is my practice to allow red meats and all others, with the exception of veal and fresh pork, at least once a day, and twice if desired. I cut off potatoes and the vegetables that grow underground, and restrict the use of sweets, thus giving my patients a generous, nutritious diet, with possibly a relative excess in the form of nitrogenized food. This form of diet seems to me to be the best, as the fundamental principle in the treatment of this class of patients is to build up and invigorate the nerve centres, increase functional activity, and thus bring nearer to the standard of health the nutritive and metabolic changes. Of course, this is only a general outline of diet. In no other part of the treatment does individualism play so important a rôle as in the matter of diet, and the requirements and idiosyncrasies of each patient must be carefully considered.

The Treatment of Chronic Gout.—Under this caption we will consider the treatment of the disease in the interim between acute attacks, when there is usually present some subacute manifestation affecting one or more joints, or there may be only deformities, the result of a previous acute attack or exacerbation. For general treatment the most important therapeutic measure is the use of mineral baths with massage and exercise, as outlined above. In addition to this, internal medication by the use of drugs will be indicated when there is present a subacute affection of one or more joints. The latter treatment may be inaugurated by a full dose of calomel at night, followed by a saline cathartic. Then the iodide of potassium and wine of colchicum may be given and continued for some time, say several weeks. I usually give from eight to twelve grains of the former with from five to ten drops of the latter, three or four times a day. I have used various other remedies, as the salicyl compounds, salicylate of colchicum, Henry's tri-iodides, etc.; but nothing has given me the general satisfaction that the iodides of potassium and colchicum have. In this condition local treatment is of considerable value. Local massage, *i.e.*, applied directly to the affected joint, if the inflammation is of a low grade, will prove of great service; but the utmost care and judgment must be exercised, lest the manipulations set up a more acute process. If there is only deformity present, without inflammation, the massage may be more vigorous, and movements of the joints with stretching of the contracted ligaments should be frequently and systematically carried out. By this means the deformities, when they are due to contraction alone, may be entirely overcome and the full use of the joint restored. Of course, if there are chalky deposits within the joint, this will be impossible, and the deposits so frequently seen about the phalangeal joints can never be removed. The application to the joint of stimulating ointments and lotions is also of considerable value. For this purpose I am in the habit of using an ointment containing iodine and iodide of potassium; this is spread on a piece of lint and applied as a plaster, and is kept in place by a flannel roller bandage, not too firmly applied. Over this I put a layer of cotton wadding and cover the whole with oilsilk. The strength of the ointment will depend upon the sensitiveness of the skin. If there is much pain in the joint, ichthyol ointment, from thirty per cent. to fifty per cent. strength, may be used instead. Acute gout may be either an attack developing *de novo*, or an acute exacerbation in a joint previously affected by the subacute form. In either case our treatment will be the same. The joint will be acutely inflamed, swollen, and exquisitely painful and tender. There will be more or less constitutional disturbance, with loss of appetite, furred tongue, restlessness, irritability of temper, and fever. The bowels may be either loose or constipated. Our efforts in treatment here will be directed to cutting short or limiting the attack, and to relieving the pain. The attack, as a rule, comes on in the early morning, and on account of the pain caused by the slightest movement we usually find the patient in bed when we pay our first visit. The affected part should be somewhat elevated by means of soft cushions, so arranged that they will allow of considerable freedom of movement, for a continued stay in one position will prove most irksome, especially as these patients are, as a rule, more or less restless. The position may better be left to the patient himself, as he will soon learn that which is most comfortable; and the clothing may be kept from the joint by means of a roomy cradle. Free purgation at the beginning of our medicinal treatment is of the greatest importance, and this is best produced by a full dose of calomel; or, if the bowels are already loose, by smaller doses carefully administered. This will prepare the way for the use of colchicum (which is undoubtedly the very best remedy for acute gout at our command), and will enable us to use smaller initial doses of the latter drug than would be possible if we depended on it alone to relieve the engorged liver and stimulate the secretion of bile. The dose of colchicum will depend upon the age and general strength of the patient. With the preliminary purgation fifteen drops of the wine will ordinarily be sufficient to begin with, and this may be increased or diminished according to its effect. The first indications of its toxic effect will be evidenced by gastro-intestinal irritation, when the dose should be immediately cut down. Sometimes it may be advisable to combine a saline purgative with each dose of colchicum, after the manner suggested by Garrod, when a much smaller dose of colchicum may be used. Relief of pain, lowering of the temperature, and a quieting of the general restlessness will follow in a very short time after this treatment has been established. If the pain persists or is unusually severe, opium may be used to control it, and in these cases I prefer Dover's powder or codeine. There are various proprietary and patent mixtures, such as Lavilles' tincture, Reynolds' specific, Blair's pills, and others, which are held in high esteem by gouty patients and are frequently used by members of our own profession; but, as the amount of colchicum which they contain and

which is their active principle is unknown, they are unsafe to use, and if for no other reason should never be prescribed. As to local treatment, in addition to the posture which I have already mentioned, much comfort can be given by fomenting the joint with hot anodyne lotions. A very useful application is the extract of belladonna in glycerin, a drachm to an ounce. This may be smeared over the joint, which is then covered with cotton wadding and oilsilk. The diet should be low, and may consist of milk alone or with Vichy, gruels, light broths, and the like, which should be taken at regular intervals. This will usually suffice until the patient is up and about, when light foods of various kinds may be allowed.

In conclusion, I would like again to remind you that, in the consideration of this subject, I have confined myself to the description of methods which have proven of greatest service in my own experience. While in the treatment of acute gout and the general care of gouty patients I may not have told you anything especially new, I have endeavored to make more clear to those of you who have not had the opportunity of observing this form of treatment the *rationale* of the bath and the importance that the proper administration of medicinal baths has in the treatment of the gouty.

152 West Forty-Eighth Street.

Progress of Medical Science.

The Effects of Small-Calibre Bullets as Used in Military Arms.—From a study of the effects produced by small-calibre bullets as used in military arms, Dr. G. G. Davis (*Annals of Surgery*, January, 1897, p. 36) reaches the conclusion that the initial force of a bullet is an onward or penetrative one; that when penetration is impeded the onward force becomes transformed into a lateral one; that explosive effect is only another name for lateral action, *i.e.*, outside the track of the bullet; that lateral action is most marked in hard bones (the fragments being carried onward) and in organs containing water (bladder, brain, liver, etc.); that practically the rotation of the bullet on its axis does not materially affect the character of the injury; that the effect of gunshot wounds is not so severe upon the living body as upon the dead; that the destructive power of the small-calibre arm has been overestimated; that its stopping or disabling power is less than that of larger calibres; that wounds in future conflicts will be as a rule less severe and will heal more rapidly, with fewer complications, than has been the case in the past; that less radical treatment will be required and conservatism will be followed by most brilliant results.

New Operative Procedure for Prolapsus of the Rectum.—Dr. Nélaton (*La Médecine Moderne*, November 7, 1896) relates the case of a man, suffering from a prolapsus fifteen centimetres in length. As the ordinary operations are almost always followed by a recurrence, Dr. Nélaton determined to try another method. He resected the rectum and the sigmoid flexure in order to fix the remaining portion to the edge of the anus. He then resected twenty-five centimetres of the intestine. In the first operation he made a section of the mesocolon by laparotomy, fixing the sigmoid after ligature of the vessels. Dr. Felizet has performed ablation for prolapsus in children by resecting the whole of the prolapsed rectum. Dr. Nélaton applies this operation to cases in which the prolapsed mucous membrane is very much hypertrophied. He says that prolapsus in the child should not be confounded with that in the adult. The latter is generally due to a defect in the tonicity of all the tissues.

Clinical Significance of the Child's Fontanelle.—Dr. Abt (*Medicine*, vol. ii., No. 11) concludes his paper on the above subject as follows: 1. Involution of the fontanelle occurs normally from the fifteenth to the eighteenth month. From birth to the ninth month the fontanelle decreases gradually in area, and from this time till complete closure the decrease is more rapid. Retardation of normal involution indicates rachitis or hydrocephalus. 2. The fontanelle presents pulsatory and respiratory phenomena. The pulsation increases if the tension is slightly increased; diminishes or is lost if the tension be greatly increased. 3. A murmur over the fontanelle occurs in a certain number of children, most commonly in those who are anæmic or rachitic. It is not pathognomonic. 4. A slightly prominent and pulsating fontanelle indicates a cerebral hyperæmia, such as occurs in fevers. 5. A protuberant and tense fontanelle indicates a exudation or inflammation in the cranial cavity. 6. Retracted fontanelle indicates a condition of collapse, brought about by acute intestinal disease with profuse watery discharges, infantile atrophy from any cause, hemorrhage, effects of prolonged acute infectious disease, or marantic sinus thrombosis. 7. In acute infectious diseases with meningeal symptoms, examination of the fontanelle shows no protuberance or tension, whereas in true meningitis these conditions are marked. 8. In the so-called hydrocephaloid, a terminal condition of cholera infantum marked by the occurrence of striking meningeal symptoms, the fontanelle is retracted.

The Treatment of Burns.—In an article upon the employment of picric acid in the treatment of burns (*Gaz. Hebd. de Méd. et de Chir.*, No. 91, 1896) Dr. Beauxis-Lagrave concludes: 1. Cicatrization of burns is more rapid with the picric-acid dressing, 5–1,000, than with any other means of treatment. The rapidity of cicatrization does not depend upon previous disinfection, since the liquid employed is sufficiently antiseptic in itself. 2. The picric acid calms the pains almost instantly. 3. The slight discoloration which the drug leaves upon the hands of the operator after its employment is not of itself a sufficient reason for not using it. 4. Picric acid is a precious drug, by reason of its low price compared with the high price of iodoform gauze; this is a very considerable advantage, if we bear in mind that almost always the victims of these accidents are workingmen. Half a litre sufficed in one instance for the dressing of a limb burned from the toes to ten centimetres above the knee.

Urethritis Due to Bacterium Coli Commune.—Josipovice (*Centralbl. f. d. Krankh. der Harn- u. Sexualorgane*, B. vii., H. 10, p. 663) reports two cases of urethritis in which he found the bacterium coli commune in the urethral discharge. In one of the cases, which he relates in detail, he was able to establish the identity of the micro-organism by cultivation. Three days after sexual intercourse the patient noted a urethral discharge which he believed to be gonorrhœal. There was increased frequency of micturition, with burning, and also constitutional disturbances, with headache and anorexia. There was slight fever and the tongue was heavily coated. The entrance to the urethra was œdematous and reddened. On pressure a drop of dirty yellow viscid pus escaped. On irrigating the anterior urethra and then receiving the urine in two parts in separate vessels the wash water was found to contain an abundance of flaky pus and threads, while the urine in both receptacles contained no threads, but was turbid and deposited a considerable sediment on standing. Seven and a half minims of sandal-wood oil in capsules were prescribed thrice

daily, with rest in bed and a diet of milk and other bland food. On the second day, although the temperature remained high, no complication could be discovered. The discharge continued in abundance and the increased frequency of micturition was a source of distress. On the third day the patient appeared brighter, with improved appetite and without fever. The discharge persisted, but it had lost its dirty color and the burning in micturition was less. By the fifth day scarcely a drop of pus could be expressed from the urethra. The first portion of urine passed now was turbid and contained threads, while the second was practically clear and free from threads. The swelling about the orifice of the urethra having subsided, injections of zinc chloride (one grain to six drachms) were begun and the disease soon came to an end. Microscopic examination of the secretion on the first day of observation disclosed the presence of bacilli coli commune but not gonococci. The examination was repeated on the following day and with similar results. Cultivation of the bacilli confirmed their identity.

Rheumatism as a Cause of Chorea.—In five hundred and fifty-two cases of rheumatic fever and one hundred and fifty-seven cases of chorea, Dr. Churton drew the following conclusions: (1) The postulated toxin (*x*) being accepted as an essential element in the causation of rheumatism, depressing conditions (*y*) determined the first position or locus of the disorder; that is, what cells or tissues (*z*) the toxin should strike. (There is probably a quite separate and independent causation for (*x*).) In ninety-one cases of rheumatism in which the incidence of the chill, strain, etc., was recorded with precision, and also the joints or parts first affected, it was seen in every case—or with very few and doubtful exceptions—that the part receiving the impact of the conditioning cause was the first to become disordered by the toxin; for example, wetting of feet always caused arthritis first in the lower extremities; of shoulders in the upper extremities. (2) If (*x*) and (*y*) are given, the position of (*z*) can be stated within certain limits. (3) If (*y*) is a fright, shock, or intense excitement, (*z*) will be the nervous system; in the developing brain of a child the result is usually chorea; in adults it may be a delirium or coma, perhaps hyperpyrexia. (4) Arthritis or endocarditis may follow the nervous disorder, since the symptoms themselves may become causes of depression of tissues, and thence of multiplication of micro-organisms and toxins. (5) Similarly chorea may follow arthritis; but (6) arthritis is never the first result of fright; and (7) chorea is never the first result of chill unless fear or brain excitement accompanies the chill. (8) A man who, being rheumatic, and having no other known disease, is accidentally subjected to strong excitement—a quarrel—and in a few hours develops chorea, is an "experiment devised by nature" to prove that the essential cause of the two disorders is the same, and that only the conditioning (localizing) causes are different. In non-rheumatic persons, even young children, brain disturbance does not cause chorea.—*British Medical Journal*, September 19, 1896.

Castration for Enlarged Prostate.—Dr. A. T. Cabot (*Annals of Surgery*, September, 1896), in an exhaustive paper on this subject, reaches the following conclusions: 1. In the matter of mortality the operation of prostatectomy has a slight advantage over castration. It seems probable that, with later statistics reflecting the last improvements in the technique of prostatectomy, this advantage would be further increased. 2. Prostatectomy has the further advantage that it allows of a thorough examination of the bladder and of the discovery and correction of other conditions not before suspected. Stones are frequently removed in this way without adding to the gravity of the operation. In several reported cases of castration the absence of improvement has led to the subsequent discovery of stones which have required other operations for their removal. 3. Prostatectomy has, on the other hand, the disadvantages that it confines the patient for a longer time and that it is sometimes followed by a fistula. This occurred in one of the forty-two cases used in this paper. 4. It is too soon to know whether any permanent loss of vigor follows castration when done on old men. The nervous effects which sometimes immediately follow the operation suggest a suspicion that with the testes the system may lose some tonic effect exerted by those organs. 5. The functional results of the two operations seem, at present, to be as nearly equal as possible, and the tendency to relapse shows itself in about the same proportion of cases after either operation. 6. The reduction in the size of the prostate after castration is largely due to a diminution of congestion. Later a degeneration and absorption of considerable portions of the gland may occur. The glandular elements are particularly affected by this atrophy. 7. Castration would seem to be especially efficacious in cases of large and tense prostates when the obstruction is due to pressure of the lateral lobes upon the urethra. 8. Castration is of but little use in myomatous and fibrous prostates. 9. Prostatectomy has its especial field in the treatment of obstructive projections which act in a valvular way to close the urethra. There is, however, no form of prostatic obstruction which a skilful operator may not correct by prostatectomy. 10. Prostatectomy is, then, applicable to more cases than is castration, and is especially to be selected when an inflamed condition of the bladder makes drainage desirable.

A Simple Method of Distinguishing Diabetic from Non-Diabetic Blood.—R. T. Williamson, M.D., London, medical registrar, Manchester Royal Infirmary (*Medical Press*), describes a simple method of distinguishing diabetic from non-diabetic blood. He has found that diabetic blood is much more powerful than non-diabetic blood in removing the blue color from a solution of methyl blue. The reaction is so sensitive that the difference can be detected by the examination of a drop of blood obtained by pricking the finger. When certain proportions of blood and a warm alkaline solution of methyl blue are mixed together, the blue color is removed in the case of diabetic blood, but remains when non-diabetic blood is used. The following is the exact method employed: In a narrow test tube are placed forty cubic millimetres of water (the capillary tube of a Gowers hæmoglobinometer, which is marked for twenty centimetres, may be used for measuring the fluid), twenty cubic millimetres of blood are added, and then one cubic centimetre of a 1 in 6,000 watery solution of methyl-blue and afterward forty cubic millimetres of liquor potassæ. The tube is then placed in a capsule or vessel containing water which is kept boiling. At the end of four minutes the blue color disappears and the fluid becomes yellow if diabetic blood has been used, but in the case of non-diabetic blood the blue color remains. In over thirty examinations of diabetic blood (from five cases of diabetes mellitus), the methyl-blue solution was always decolorized; while normal blood and the blood from one hundred patients suffering from the most varied diseases never decolorized methyl blue when mixed in the above proportions. Hence, by this simple method, a drop of blood from a well-marked case of diabetes mellitus may be readily distinguished from non-diabetic blood.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHERS

WM. WOOD & CO., 43, 45, & 47 East Tenth Street.

New York, February 6, 1897.

THE GENERAL PRACTITIONER.

It was rather a remarkable coincidence that two of the orators at the recent semi-centennial of the Academy of Medicine, in their efforts to touch upon subjects of vital interest to a general audience, should speak of the present and much-neglected claims of the general practitioner. President Cleveland, in sounding the praises of the old-school doctor who met all the emergencies of treatment in the last generation, implied a personal feeling of regret that the trustworthy and practical man, ready for every ordinary sickness, had virtually passed away with the times in which he had so usefully lived and had so prosperously thriven. Dr. Jacobi, in a more direct way, speaking for the actual needs of the medical practice of to-day and giving specialism its due meed of praise, expressed himself strongly in favor of reinstating the all-around man.

These ideas are not new; they have been presented often enough before, but hardly with such opportunities for wide dissemination in the daily press which the occasion of their deliverance would seem to demand. The general aspect of this question has been often enough discussed in these columns, but the present opportunity brings with it the usual temptation for a few more words on the pros and cons. No one doubts that specialism has helped very materially to advance scientific medicine and surgery, but all equally admit that it has been very much overdone. Especially has this been the case with the younger men in such lines, who take up the serious study of their particular branches of work immediately after leaving the medical school and commence at the smallest possible end of their opportunities for broad culture. Proper specialism is but a graft upon general knowledge and practice, and cannot consistently succeed under any other conditions of growth. It can never exceed the sources of real nourishment at the original root. Hence the most prosperous specialists are those who have grown into their work by the accidents or necessities of their surroundings. Such men do not magnify their office, and, while being specially fitted for the treatment of certain diseases requiring particular skill, are always ready and willing to view the body as a whole and the local difficulty as the necessary part.

There is, however, not so much need of this form of special work as for the more distributive kind of service which the general practitioner is abundantly qualified to render. It is in the treatment of the commoner diseases that the family physician finds his best opportunities for usefulness and his best prospect for continued progress. His skill is in generalizing and adapting, and this in the great majority of cases is all that is necessary to cure his patients. If he be a well-educated man, a careful observer, a progressive student, and a practical therapeutist, he safely pursues the even tenor of his way, and reaches a higher average of actual cure than many of those who so constantly preach to him of his shortcomings. It is quite true that there are a given number of cases requiring special skill, but these are not numerous enough seriously to hamper general practice. It is by no means impossible for the family physician to adapt himself to all the ordinary emergencies of a general practice, whether it be in the lines of medicine or surgery. The country practitioner does this everywhere, and is, unfortunately, the only type of what is fast becoming an extinct species of medicine man. His views of treatment must necessarily be broad and conservative. He is never a crank—a man with one idea. What is best to do in any case is always qualified by existing circumstances. In proportion as he is able to apply the latter, he is a safe man. Fortunately, the really necessary and usual work of the general practitioner is easily done. He has a comfort in knowing that most of the very rare diseases are not curable, that the commoner ones have well-recognized rules for treatment, and, best of all, that the rational adaptation of established methods are within easy reach of all. Therefore we say, in echoing the sentiments of the speakers, give the general practitioner a chance.

THE HEALTH BOARD AND PULMONARY CONSUMPTION.

Since we took occasion to comment on the ill-advised determination of the health board to assume an official control of phthisis patients, we have received a large number of letters endorsing our views and approving the course taken by us. It has left no doubt in our mind that the profession here and elsewhere is inclined to the belief that the actual necessities for the measure are very much exaggerated and out of all proportion to the good results that are promised. As an instance of the current of opinion we quote the following, received from a well-known medical gentleman of Chicago:

"It is with much satisfaction that I have read your editorial in last week's MEDICAL RECORD, in protest against the action of your board of health in the matter of pulmonary tuberculosis.

"It seems to me that our various boards of health are in great danger from the unscrupulous and ignorant political doctor on the one hand, and from the idiot savant on the other. In many of these organizations we find some clever bacteriologist, who is an expert with the microscope and test tube, but who has

not sufficient knowledge of human nature to secure a living outside of the laboratory in which he is employed. It is a real misfortune when these people are allowed full swing. If the boards of health be permitted to exercise such authority, the liberties of the medical profession will vanish into thin air, and we shall have to practise according to the dictates of some insignificant secretary, who has arrogated to himself the powers of a board of which he is not even an official member.

"I doubt not, if your board persists in its course, that it will soon be able to report an enormous reduction in the number of cases of pulmonary tuberculosis in New York. They will die all the same, but they will not die of tuberculosis—just as scarlet fever and diphtheria in Chicago have become infrequent, because only reported when it is safe to do so. In the mean time, what is to be said in favor of wholesale education of the medical profession into habits of evasion and contempt for sanitary authority? What will become of popular confidence in the inviolability of medical secrets, when the unfortunate victim of incipient tuberculosis finds himself under police surveillance as a consequence of asking counsel of his family physician?"

These are very pertinent questions at this time. If they in any degree pertain to motives actuating our own board, it may be prudent for it to wait and look before it is too late to jump back gracefully.

SHALL CLERGYMEN ADVERTISE?

In one of the denominational papers appeared the following:

"The rector of a small parish desires to obtain a larger field of labor in town or country. Young, active, and energetic, of sound churchmanship and good preaching ability. Highest credentials from present bishop and vestry. Address 'Clerical Craftsman,' — — office."

Although there has long been a natural desire on the part of ambitious clergymen to be the willing victims of larger fields of work and proportionately greater opportunities for usefulness, until lately such bids for worldly favor were charitably construed by unenvious brethren as evidences of a laudable desire to extend Christianity and occupy the earth. Now, however, the Episcopal Convention of Nashville, Tenn., has taken official notice of the scheme and it has been called by the harsh name of advertising. It is pleasing to note, in the report of the committee appointed to investigate the charge, that neither the legal nor the medical profession permits such doings. The report quite significantly says:

"In its lack of an ethical code the ministry suffers by comparison with the other learned professions. In the codes of the professions the restrictions upon advertising are important features. It is well known what a brand is placed upon a physician who advertises. What would be thought of the physician who advertised himself as unmarried, and, therefore, able to render his medical services cheaper than his married fellow-practitioners?"

We are glad to know that the profession of medicine, which is always said to be the second on the list of usefulness and respectability as compared with the clerical calling, has not yet descended to such straits. What would be good for an unmarried clergyman would not be advantageous for an unmarried doctor, so far as business patronage is concerned. In the former case the church would be full, and in the latter the office empty. Why not permit the struggling clergyman to advertise a sermon now and then, just as the surgical aspirant does with an equally sensational operation?

FOR THE PROTECTION OF HOSPITAL PATIENTS.

The failure of the London nurse who attempted to obtain damages from an operator for exceeding her wishes has resulted in the formation of a Society for the Protection of Hospital Patients. It has been claimed that the brutal doctors have had their way long enough, and that the time has arrived when the "clinical material" can talk back. With a becoming sense of his real importance, the hospital patient is beginning to assert his rights. He appreciates the fact that he is so necessary to the hospital man that the latter cannot do without him, and, in consideration of the favor of yielding himself to free treatment, he must have the right to call his benefactor to account. Thus he may dictate his treatment, question his doctor's ability, sue him for any supposed neglect, and claim damages even for skilful services conscientiously rendered in the name of charity. In order that the work of the attending physician or surgeon may be properly done, it will possibly be necessary for some walking delegate to accompany the doctor in his ward visits and regularly report to such of the patients as may be members of the union. What the members may save by free treatment can thus be used for prosecuting purposes. We can only congratulate ourselves that no similar organizations exist on this side of the water, as the free patients are much richer here and consequently more powerful.

Medical Practitioners in Germany.—According to Börner's Medical Directory, the number of registered medical practitioners in Germany is 24,000, an increase of nearly 1,000 during the past year and of nearly 8,000 during the past ten years. Of this number, 14,351 are in Prussia, 2,643 in Bavaria, 1,766 in Saxony, 934 in Baden, 800 in Würtemberg, and 722 in Alsace-Lorraine, the remainder being in the smaller states of the confederation. There were 2,289 medical men resident in Berlin at the end of last year, 523 in Munich, 487 in Hamburg, 447 in Breslau, 368 in Leipzig, 354 in Dresden, 292 in Frankfort, 257 in Cologne, 225 in Hanover, and 179 in Strassburg. The average number of practitioners is 4.59 for each 10,000 inhabitants, but this proportion varies very much according to the locality, being in Berlin 12.38.

News of the Week.

Ureteral Catheterization in Women.—In the issue of the MEDICAL RECORD for January 23d, there appeared a short item in which an injustice was inadvertently done Dr. Howard A. Kelly, of Baltimore, in the suggestion that the credit for his work in catheterization of the ureters might belong to Pawlik, of Prague. The question is one which has been under discussion in the gynecological journals for a year or more, but it may now be regarded as closed, for Dr. Kelly has most abundantly and conclusively proved his own claims to originality and disproved the charge of plagiarism brought by Pawlik. The latter did several years ago catheterize the ureters in women, but his method and his instruments were no more like Dr. Kelly's than a crowbar is like a diamond drill. Those interested in the subject may read the claims of both parties to the controversy in the *Centralblatt für Gynäkologie*, Nos. 19 and 50, 1896, and in the *American Journal of Obstetrics*, No. 3, vol. 33, and No. 2, vol. 34, 1896.

The Spread of Leprosy in Hawaii.—In a letter to Dr. Ashmead, of this city, Dr. Mouritz, of Molokai, says that that place is one of the best fields for observing the penalty the human race is paying for its apathy in dealing with leprosy. The lepers at Molokai number between eleven thousand and twelve thousand, chiefly natives; but within a year or two the disease has begun to make inroads upon the white population. The law of segregation was for a long time very loosely enforced, and, although the condition is better to-day, isolation is still far from thorough and effectual. The increase in the number of lepers in Colombia has been, Dr. Ashmead writes, from four hundred to twenty-seven thousand, not to twenty-seven hundred, as was incorrectly stated in his letter published in these columns on January 23d.

Obituary Notes.—DR. ALBERT W. KILBOURNE died, January 14th, at his home in Liberty, N. Y., of aneurism of the heart. He was born in Liberty in 1851, and was graduated from the medical department of the University of New York in 1874. He practised in Albany for twenty years. Three years ago his health began to fail, and he then returned to his old home in Liberty. He never married.—DR. FRANCIS M. LORETTO died at his home, 495 Third Street, Brooklyn, on Friday, aged eighty-four years. He was born in London. He had practised medicine for fifty years when he retired, ten years ago. Three daughters survive him.—DR. ZEDKAUER, who, the cable states, was the private physician of the Tsar, died in St. Petersburg on January 28th.—SIR THOMAS SPENCER WELLS died a few days ago at Antibes, France. He was born in 1818, and was educated at Trinity College, Dublin. He was president of the Royal College of Surgeons in 1882–83. He was surgeon to Her Majesty's household. At the third centenary of the University of Leyden and the eighth of the University of Bologna, he received the degree honorary of M.D. The University of Charkoff also conferred an M.D. upon him, and Dublin made him an LL.D. Queen Victoria, in April, 1883, conferred upon him a baronetcy in acknowledgment "of the distinguished services which he has rendered to the medical profession and to humanity." He was the author of several works on abdominal surgery. He made a brief stay in this city about a year ago, on his way home from a visit to Jamaica and Florida.—DR. SOLOMON DEUTSCH, whose "Letters for Self-Instruction in German" and "Medical German" have helped many physicians and others over the difficult beginnings of colloquial German, died in this city on January 29th. He was born in 1816, and came to this country in 1857. At first a rabbi, he abandoned his religious work many years ago on account of his liberal views.—DR. BENJAMIN B. ADAMS, of Washington, D. C., but formerly of Philadelphia, died suddenly on January 25th, at the age of forty-six years.—DR. FRANK A. BIRRIOLO, of Blossburg, Pa., died at Trenton, N. J., on January 21st, from cerebral hemorrhage, at the age of twenty-six years.—DR. JOHN KIRKER died at Allegheny City, Pa., on January 23d, at the age of about sixty-one years, as a result of an attack of erysipelas. He served as a surgeon in the United States army during the war of the rebellion.—DR. W. S. ROLAND died at York, Pa., on January 23d, at the age of eighty-three years. He had been for a number of years a member of the State board of agriculture.—DR. THOMAS G. ROWAND died at Camden, N. J., on January 25th, at the age of sixty-eight years. He was graduated from the Philadelphia Medical College in 1850, and was one of the physicians to the women's department of the Southwark Hospital during the prevalence of the scourge in 1849. He was elected coroner of Camden in 1854 and again in 1868. In 1857 he was commissioned deputy quartermaster-general of the Camden brigade, New Jersey militia. In 1859–60 he was professor of materia medica, pharmacy, and general therapeutics in the University of Pennsylvania. In 1862 he was commissioned assistant surgeon in the twenty-fourth regiment, New Jersey volunteers, remaining with his regiment until it was mustered out of the service. He was also detailed as a surgeon in the hospital of the third division of the second corps, at Potomac Creek, Va. In 1867–68 he served as president of the Camden board of education.

"New Yorker Medicinische Monatsschrift."—Dr. Otto G. T. Kiliani, who has for some years most ably conducted this journal, has retired from the editorship, being succeeded by Dr. Alfred Michel. The *Monatsschrift* is the official organ of the German Medical Society of New York.

The Plague.—According to the official report issued January 28th, there have been 4,396 cases of the plague in Bombay and 3,275 deaths from that disease. At Kurrachee, 694 cases and 644 deaths have been recorded. At Poonah there have been 65 cases and 60 deaths, and a few cases have occurred at Surat, Baroda, Ahmadabad, Kathiawar, and Cutch. Three deaths have also occurred at Goa, the capital of the Portuguese possessions in India. The plague has

broken out in the island of Formosa, recently acquired by the Japanese from China. The German government is about to send a special commission to Bombay to investigate the bubonic plague, with a view of adopting precautionary measures against the introduction of the disease into Europe. Dr. Koch has been summoned from South Africa, where he has been studying the rinderpest, to head the commission. As an instance of the alarm felt in Europe, it is said that an Englishman from Bombay, who arrived at Milan from Brindisi in a second-class railway carriage, was for a long time refused a permit to cross the frontier.

Death of Dr. Richard J. Hall.—Dr. Richard J. Hall, aged forty years, formerly of New York, son of Rev. John Hall, of New York, died at Santa Barbara, Cal., on the 24th inst., of tuberculous disease of the intestine. He was compelled to give up his practice in New York six years ago on account of failing health, and went to Santa Barbara, where he applied himself to the practice of surgery. He became the foremost citizen in Santa Barbara, and a most public-spirited man.

The State Medical Society.—The recent meeting of the Medical Society of the State of New York was the occasion for the usual rush of papers and the correspondingly limited time for their reading. It is a great pity that the different business committees cannot make better arrangements for a more deliberate and dignified discussion of the topics presented. There is such a desire to make a good showing in the number of subjects presented that everything appears to be managed on the ten-minute-refreshment plan. The consequence is that the man who goes to Albany to read a paper that has taken him a month to prepare has hardly time to introduce his argument before he is warned to stop and give place to the next on the anxious list. It is absurd to suppose that any real good can come of this method. In the effectual remedying of such a growing evil rests the future usefulness of the society as a leading scientific body.

Small-Pox in Pueblo.—There were two hundred and seventy deaths from small-pox in Pueblo, Mexico, during the first half of January. Most of the sufferers are among the poorest class of the Indians, and the spread of the disease is insured by the custom of carrying the dead to the cemetery in coffins on the heads of surviving friends.

Associated Health Authorities of Pennsylvania.—The fourth annual meeting of the Associated Health Authorities of Pennsylvania was held at Harrisburg on January 25th and 26th. An address of welcome was delivered by Governor Hastings, and the following communications were presented: "The Necessity of Physical Education in the Public Schools," by Randolph Faries, M.D.; "Unfiltered Water Always Unsafe for Town Supply," by Henry Leffmann, M.D.; "The Monetary Loss to Cities from Typhoid Fever," by Thomas Turnbull, M.D.; "Rendering Wall-Paper Impervious to Disease Germs;" "The Prevention of Certain Diseases of the Eye in Certain Classes of Children," by W. Campbell Posey, M.D.; "Some of the Trials of a Country Board of Health," by J. G. Shoemaker, M.D.; "The Registration of Midwives," by A. C. Wallace, M.D.; "Remarks on the New Disinfectant, Formaldehyde," by Benjamin Lee, M.D.; "Should the Erection of School Buildings be Regulated by Act of Assembly?" by A. M. Sloan.

The Physician's Responsibility for an Incorrect Diagnosis.—The question of the liability of physicians for the results of their unskilful or negligent treatment of patients has again been before the law courts in England. The correspondent of the *Sun* relates the following case: The children of a lawyer in Bangor fell ill of a disease which the family physician diagnosed as "malignant sore throat." The six-years-old boy died within a few days, and the six-months-old baby died later, according to the doctor, of laryngitis and bronchitis. Meantime, as the disease was not considered infectious or contagious, no precautions in the way of isolation were carried out, with the natural result that other members of the household fell ill, although the doctor repeatedly declared that no danger existed for anybody. When the anxious father had lost his two children he thought it about time to have additional advice, and the new doctors instantly diagnosed diphtheria as the cause of the trouble. The father brought an action for damages, and there was an array of experts on both sides. Dr. Lennox Brown pronounced the disease to be diphtheria. He had analyzed a portion of one little victim's membrane, and found the Klebs-Loeffler bacillus. But other experts were produced on the other side, the jury became hopelessly confused, and the trial ended in a judgment for the defendant.

St. Luke's Hospital, New York.—Dr. Pearce Bailey has been appointed consulting neurologist to St. Luke's Hospital.

The Association of Military Surgeons of the State of Ohio.—In response to a call of the surgeon-general of the State, the medical officers of the Ohio National Guard met in the State House, Thursday afternoon, December 17, 1896. A constitution and suitable bylaws were adopted, forming the Association of Military Surgeons of the State of Ohio, the active members consisting of the medical officers of the Ohio National Guard, and the associate members of ex-medical officers of the Ohio National Guard and ex-medical officers of the United States volunteer service; provision was also made for honorary members. The following officers were elected: *President*, Brig.-Gen. J. E. Lowes, Surgeon-General of Ohio, Dayton; *Vice-President*, Maj. L. T. Guerin, Surgeon Fourteenth Infantry, Columbus; *Secretary*, Maj. H. M. W. Moore, Surgeon First Light Artillery, Columbus; *Treasurer*, Maj. Frank Bain, Surgeon Second Infantry, Kenton; *Executive Committee*, the foregoing officers and Maj. E. C. Farquhar, Surgeon Eighth Infantry, Zanesville; Capt. Gilbert I. Cullen, Assistant Surgeon, First Infantry, Cincinnati; Lieut. (junior grade) C. W. Newton, Surgeon First Battalion, Naval Brigade, Toledo. Lieut.-Col. William E. Waters and Capt. James E. Pilcher, of the army, were elected honorary members.

The Health of the Tsar.—The report that von Bergmann had been summoned from Berlin to St. Petersburg to remove a bony growth from the head of the Tsar is now denied. The St. Petersburg correspondent of the London *Daily Telegraph* has had an interview with the Tsar's physician in ordinary, who said: "His Majesty has not even asked medical advice. But it is true that he feels every sudden change in temperature through the wound he received in Japan, mostly in the form of neuralgia, and he has even been known to swoon. But for the moment he is quite free from any nervous disorder or from the symptoms of any malady whatever."

A Bill to Regulate the Practice of Medicine in Colorado.—A new bill, or rather an amended bill, to regulate the practice of medicine in Colorado will be introduced in the legislature in a few days, by the legislative committee of the Colorado State Medical Society. The main features of the new bill will be the doing away of the ten-year clause and the requiring of all physicians to be graduates of reputable medical colleges before they can be admitted to the board for an examination for a license to practise medicine in this State.—*Denver Medical Times.*

Lord Lister is the title which Sir Joseph Lister has assumed, and not Lord Kinnear, as was announced by the cable at the time of his elevation to the peerage. We are glad that this is so, for the name of Lister has been made too noble by noble deeds to be laid aside for any other.

The Jenner Centenary in Russia, after several postponements, was finally celebrated in St. Petersburg on January 3d, by a meeting at which the Grand Duke Paul presided. The celebration was arranged by the National Health Society of Russia. Several eulogies of Jenner and speeches referring to the discovery of vaccination were delivered. The bust of Jenner was placed at the upper end of the hall in which the meeting was held. Upon the walls were diagrams and tables of statistics, and an exhibition of objects connected with vaccination was afterward opened.

"The Scottish Medical and Surgical Journal" is the name of a new monthly publication edited by Dr. William Russell, of Edinburgh, assisted by a staff of collaborators in other parts of Scotland.

Manhattan State Hospital.—Dr. Percy Bryant, of Buffalo, N. Y., has been appointed from the eligible list of the State civil service commission to the position of medical superintendent of the Manhattan State Hospital, with salary of $2,500 per annum. Dr. Bryant, who is now first assistant at the Buffalo State Hospital, was born in Cedar Falls, Iowa, in 1863, and graduated from the medical department of Columbia in the class of 1887.

Navy Department, Bureau of Medicine and Surgery, Washington, D. C. Changes in the medical corps of the United States navy for the week ending January 30, 1897. January 23d.—Assistant Surgeon C. E. Biggs detached from the *San Francisco* and ordered to the *Detroit.*

An Anti-Cigarette Bill has passed the lower house of the Tennessee legislature by a unanimous vote, and it is expected that it will also pass the Senate. It prohibits absolutely the sale of cigarettes and of cigarette papers in the State. The law is to come into effect May 1, 1897.

Skiagraphing the Brachial Artery.—It is reported in the papers that Superintendent Knoll, of the Hudson Street Hospital in this city, has obtained a clear skiagraph of the calcified brachial artery in a man eighty years of age.

Tri-State Medical Society.—The fifth annual meeting of the Tri-State Medical Society of Iowa, Illinois, and Missouri will be held in St. Louis, April 6, 7, and 8, 1897. A large number of valuable papers will be read. The officers are: *President*, Dr. A. H. Cordier, Kansas City; *First Vice-President*, Dr. Hugh T. Patrick, Chicago; *Second Vice-President*, Dr. H. C. Eschbach, Albia, Iowa; *Secretary*, Dr. G. W. Cale, 4403 Washington Boulevard, St Louis; *Treasurer*, Dr. C. S. Chase, Waterloo, Iowa.

A Tale of Quackery in Berlin.—The death of General v. Lippe, one of the personal aides-de-camp of the German emperor, which took place a few days ago in Dresden, closes a curious story of quackery versus the profession. In February last Herr v. Lippe, who suffered from an organic disease of the spine, entered the Augusta Hospital (Berlin), and put himself under the treatment of its directing physician, Professor Ewald. A consultation with Professor Jolly took place, and both doctors agreed entirely both as to diagnosis and prognosis. The progress of the disease was so clear that Professor Ewald spoke of its serious nature and probably fatal ending to the patient's wife, at the same time proposing another consultation with a recognized authority. But Frau v. Lippe declined this, and called in a "nature doctor," Goessel, from Dresden, a quack who is in the habit of diagnosing his patients' diseases from the stockings they have worn. Of course, Ewald declined to consult with him, and retired from the case, and it seems strange that under the circumstances Herr v. Lippe was not removed from the Augusta Hospital. Whether—as is said—feelings of humanity induced the hospital authorities to keep him where he was, or whether—as seems more likely—pressure was brought to bear on them from higher quarters, certain it is that Herr v. Lippe remained in the hospital, as if in private apartments, with an attendant of his own, with his food sent in from the royal kitchen, and with his own "nature doctor" in attendance. After some weeks of so-called "cure," he was said to be progressing toward recovery, and he left the hospital and Berlin, and settled down in Dresden to be near his "doctor." After a few months of ups and downs, the disease has now run its course and the sufferer has died. The moral of the story is, of course, that no amount of prohibitive legislation will be able to put down quackery as long as it is believed in and favored in the highest social circles.—*Berlin Correspondence, British Medical Journal.*

Reviews and Notices.

Medical Jurisprudence, Forensic Medicine, and Toxicology. By R. A. Witthaus, A.M., M.D., and Tracy C. Becker, A.B., LL.B., and a staff of collaborators. In four royal octavo volumes. Volume IV., Toxicology. New York: William Wood and Company. 1896.

The entire contents of this volume of almost nine hundred pages appear to have been written by Professor Witthaus himself—at least his is the only name which appears after the title page, which bears besides the name of Professor Becker, of the University of Buffalo, a long list of collaborators from the legal and medical professions. After a few pages of introduction and a long bibliographical list of ancient and modern works, comes the chapter on general toxicology, and in turn special toxicology, mineral poisons, vegetable poisons, animal poisons, and synthetic poisons. In no branch of medical science is accuracy of greater importance from the author's side, for here it is not a question of personal belief for which the writer may be excused for differing from his neighbor. Scientific facts which may be worked out in the laboratory and subjected to proving-tests are largely dealt in, and, being intended for an accurate guide in courts of law, must be most carefully stated. The volume before us bears upon every page those evidences of painstaking preparation which alone can make such a work valuable. Strangely enough, the words "toxin" and "antitoxin" do not appear in the index, though ptomains are mentioned a number of times. The chapter on poisoning from foods is shorter than the importance of the subject warrants, but this is made up for in part by generous bibliographic references. *Finis coronat opus*, and if we may judge of the three volumes which have already appeared by the one before us the authors of this "Forensic Medicine" have just cause for self-congratulation upon the completion of a worthy work.

The Diseases of the Male Urethra. By R. W. Stewart, M.D., M.R.C.S., Surgeon to Mercy Hospital, Pittsburg, Pa. New York: William Wood and Company. 1896.

Since the introduction in late years of improved instruments for the observation and investigation of the urethra, much has been learned that was formerly guessed at. The ultimate results have not always been so brilliant as the advances in methods would seem to call for; however, the surgeon of today may have the satisfaction of knowing that he is pursuing lines of treatment based upon sounder pathology, and hence more scientific, even if not invariably more successful. In the twenty-six chapters crowded into the two hundred and twenty pages of this work, which forms one of "The Medical Practitioner's Library" series, the author has kept well before him the aim of making a modern exposé of urethral diseases and their cure, omitting the really rare affections as belonging to the large works. Considerable attention has been paid to the relation of gleet to strictures in the canal. Such frequent advice is given "to the beginner" that one is led to believe that the author intended his treatise for the use of the student as well as for the actively engaged practitioner.

An American Text-Book of Physiology. Edited by William H. Howell, PhD., M.D., Professor of Physiology in the Johns Hopkins University, Baltimore, Md. Fully illustrated. Philadelphia: W. B. Saunders. 1896.

The contributors to this large work include the names of Bowditch, of Harvard; Curtis, of Columbia; Donaldson, of the University of Chicago; Lee, of Columbia; Lombard of the University of Michigan; Lusk, of the Yale School; Porter, of Harvard; Reichert, of the University of Pennsylvania; and Sewall, of the University of Denver. To those familiar with the work of the contributors we need say little in commendation of what they have here written. Those who have studied under Bowditch know that his contribution would be nothing if not good. Those who learned their physiology from John G. Curtis would feel confident that his chapter on the mechanics of the circulation of the blood and of the movements of the lymph would be worth reading, and so it is.

Professor Howell has not been the editor alone, but we are pleased to find chapters on secretion, chemistry of digestion, movements of the alimentary canal, of the bladder and ureter, and blood and lymph, all from his pen. There is no question that there are advantages in having certain large works produced by the collaboration of many writers. Indeed, a broad subject like this cannot be treated to such advantage by one author, within reasonable limits of time. The overlapping of topics is, however, a decided disadvantage to the student, who has no time to read views of two teachers upon the same subject which are, perhaps, opposite, and then decide for himself. Perhaps this is unavoidable, but in the present work it has happened in several instances.

Another disadvantage for the student is the size and weight of the volume. If published in two or even three volumes, the additional expense to the student would be money well invested. He could then take back and forth between his room and the college or laboratory the volume containing the subjects being studied. Most students would break down under the attempt with the volume as it now is.

Traité de Chirurgie Clinique et Opératoire. Publié sous la direction de MM. A. Le Dentu et Pierre Delbet. Tome premier: Pathologie Générale. Maladies de l'Appareil Tégumentaire. Par MM. Nimier, Ricard, Faure, Le Dentu, Lyot, Brodier, et Delbet. Paris: Librairie J.-B. Baillière et Fils. 1896.

This first of what promises to be an important work of some ten or more volumes is divided into two sections, one devoted to general surgical pathology covering nearly seven hundred pages, and one dealing with special surgical pathology, of which the diseases of the integument take up the remaining hundred or more pages. Sixty-four woodcut figures and engravings are scattered throughout the text. One of the editors, Dr. Delbet, has contributed a most praiseworthy chapter upon the difficult subject of neoplasms. It is the longest chapter in the volume. The diseases of the skin have received careful consideration from the pen of Dr. J. L. Faure, and especially in their surgical aspects. The contributors to this and subsequent volumes include the names of Albarran, Arron, Binaud, Brodier, Cahier, Castex, Chipault, Gangolphe, Pichevin, Ricard, Rieffel, Schwartz, and Villar. Dr. A. Le Dentu, who is likewise one of the editors, furnishes the present chapter on lesions by destruction of tissue, including injuries by burning and freezing. Interesting chapters on gangrene, ulcers, fistulæ, and cicatrices have been written by Dr. C. Lyot. The print is good, but the cover is of paper, as is usual in French works, and necessitates binding before any real use can be made of the book.

Premature Burial, and How It May Be Prevented. By William Gebb, F.R.G.S., and Col. Edward Perry Vollum, M.D., late Medical Inspector, U.S.A. London: Swan, Sonnenschein & Co., Ltd. 1896.

This work has special reference to trance states, catalepsy, and other forms of suspended animation. The major part is made up of the writings of authors of the past, but each of the present writers has personal experience of interest to relate, one of them having been himself "laid out for dead." The pages are replete with instructive though at times grewsome details, and the subject is one of such vast importance that it would be well for all medical men who are not already familiar with its literature to read the book and remember the lesson it teaches. Anything must be welcome which will tend to remove the senseless fear of the dead and prevent friends from deserting the bedside the moment life is supposed to be extinct, giving over the body to those who will immediately take steps to complete the extinction rather than to fan back into life any spark of vitality which may remain in a doubtful case.

A Treatise on Surgery by American Authors, for Students and Practitioners of Surgery and Medicine. Edited by Roswell Park, A.M., M.D., Professor of the Principles and Practice of Surgery and of Clinical Surgery in the Medical Department of the University of Buffalo, etc. Vols. I. and II. Philadelphia and New York: Lea Brothers and Company. 1896.

Volume I. treats of general surgery and is illustrated with three hundred and fifty-six engravings and twenty-one full-page plates in color and monochrome. The contributors to this volume include Belfield, Burrell, Eve, Fordyce, Gerrish, Hardaway, Hare, Holloway, Mudd, Nancrede, Park, Parmenter, Ransohoff, Smith, and Souchon.

Such advances are to be noted in the surgeon's work of late years that we find marked evidences of specialism in this department of medical science, and a work to claim anything approaching completeness must deal with many subjects from this exclusive side. In this way only is it possible to complete a large text-book within reasonable limits of time and present the material in a fresh form. When the editorship is assumed by a man of such recognized ability as in the present instance, we have warrant for an *a-priori* judgment that the work of all contributors has been satisfactorily accomplished. Volume II. treats of special or regional surgery. Besides several of the names already mentioned we find those of Bevan, Blake, Bradford, Bull, Delavan, Dennis, Etherbridge, Gerster, Kelsey, Lovett, Matas, Parker, and Richardson attached to the respective subjects with which they are more or less identified. Thus, Maurice Richardson writes upon the surgery of the abdomen, and in the task has had the assistance of Farrar Cobb. He also has a chapter upon hernia. Charles Kelsey contributes an article on diseases of the rectum and sigmoid flexure. William T. Belfield has genito-urinary surgery, Gerster plastic surgery, and so on. Roswell Park himself has written a number of chapters in each volume, and has shown excellent judgment in the selection of co-workers and the arrangement of the plan and scope of the whole work. The illustrations are for the most part excellent, and the publishers' part has been done in such a way as to make a very attractive production. Some over-lapping and separation of subjects, so that both volumes must be consulted in order to learn all that has been said upon a given topic, are a necessary outcome of this system of book-making which is here and there noticeable. Such chapters as those upon auto-intoxications and surgical pathology of the blood as well as the frequent references to modern bacteriology point to the advanced scientific thought which has permeated the work as a whole. The volumes may be procured separately, and have been prepared with the view of being independently useful.

Der Praktische Arzt als Augenarzt. Von Dr. Med. J. Hell, in Ulm. Ravensburg: Otto Maier. 1897.

A short useful handbook for practising physicians upon the common eye diseases.

The Physician's Visiting List for 1897. Forty-sixth Year of its Publication. Philadelphia: P. Blakiston, Son and Company.

This popular visiting list is again published, with all its well-known features of practicality and simplicity conspicuously retained. There is very little text to encumber its pages, which are meant to be filled up by the physician on his daily rounds.

Self-Instruction in the German Language. Deutsch's Letters; a Practical Method for Easy and Thorough Self-Instruction. By Solomon Deutsch, A.M., Ph.D., Author of "Medical German," "A Practical Hebrew Grammar," etc. Second and Revised Edition. New York: J. H. Vail and Company. 1896.

This work has been prepared with special regard to the close affinity existing between the English and German languages. The value of this work, which has been well received, has been increased in the second edition by the "Key to the German Exercises," which has been appended. The student can make use of this innovation to retranslate. Physicians studying German will find this an exceedingly useful work, and even those who know much of the language already will be interested in the many analogies with other languages and points of interesting importance which are referred to.

Reference-Book of Practical Therapeutics. By Various Authors. Edited by Frank P. Foster, M.D., Editor of the *New York Medical Journal* and of *Foster's Encyclopædic Medical Dictionary*. In Two Volumes. Vol. I. New York: D. Appleton and Company. 1896.

The plan of this work is one that will commend itself to the practitioner who desires to refresh his knowledge of the uses of the standard therapeutic agents, or to learn of those of the more recently introduced drugs, with the least expenditure of time and of labor. The arrangement of titles is alphabetical, and numerous cross-references direct the reader to the desired article without waste of time in a mental search for synonyms. All agents, ponderable and imponderable, which are employed in the treatment of disease are here included, with the exception of some of the most recently introduced synthetic products, the value of which is as yet undecided. Several of the drugs admitted to the book are proprietary articles of unknown composition, which are officially condemned by the American Medical Association and in daily use by many of its members. In the difficult task of deciding which of these is worthy of recognition the editor has, it seems to us, exercised good judgment in the main, although necessarily there will be differences of individual opinion in such a matter. The present volume carries the work through M. The second volume will contain an index of diseases, which will make the mass of useful information here contained of practical application.

A Monograph of Diseases of the Nose and Throat. By George H. Quay, M.D. Philadelphia: Boericke & Tafel. 1897.

This is a book of two hundred and fourteen pages, especially adapted to the needs of the student and general practitioner. In it one finds enough anatomy and physiology to enable the reader to comprehend the text, also the methods of examination. It is concise, well written, and certainly should meet the demands of the busy practitioner who has not the time to consult a more voluminous work on this subject.

The Sequels of Disease. Being the Lumleian Lectures delivered in the Royal College of Physicians, 1896. Together with Observations on Prognosis in Disease. By Sir Dyce Duckworth, M.D., LL.D., Fellow and Treasurer of the Royal College of Physicians; Physician and Lecturer on Medicine, St. Bartholomew's Hospital; Sometime President of the Clinical Society; Hon. Physician to H.R.H. the Prince of Wales. London: Longmans, Green and Company. 1896.

It is not often that we see a more interesting book on a purely medical subject than this. The author has a pleasing style which is a good setting for any subject, however dry, but here the subject is novel and could scarcely avoid being interesting, even in the hands of a poor writer. The author says that he was led to take up this subject by a remark of Dr. William Baly that one of the most useful books that might be written would be one on the diseases of convalescence. The importance of this subject is shown by the seeming paradox that persons rarely die of the disease from which they suffer, but of some secondary trouble, a sequel or a complication of the primary affection. The second and shorter section is on prognosis, being substantially the address delivered by Sir Dyce Duckworth before the British Medical Association in 1896. The book is handsomely printed on heavy paper with rough edges, and is a joy to the eye as well as a source of instruction and entertainment of the mind.

A System of Gynæcology. By Many Writers. Edited by Thomas Clifford Allbutt, M.A., M.D., LL.D., F.R.C.P., F.R.S., F.L.S., F.S.A., Regius Professor of Physic in the University of Cambridge, Fellow of Gonville and Caius College, and W. S. Playfair, M.D., LL.D., F.R.C.P., Professor of Obstetric Medicine in King's College, and Obstetric Physician to King's College Hospital. New York: The Macmillan Company. 1896.

This treatise on gynæcology which forms the second volume of "A System of Medicine," edited by Dr. Allbutt, is the work of twenty-six authors, most of them well-known British gynæcologists. According to the publishers' prospectus, there are to be two volumes devoted to gynæcological subjects, but this one appears to cover the ground so completely that we cannot imagine where material can be found to fill a second volume, unless it is to be devoted to obstetrics. The articles are of varying merit, as is to be expected in a work of this sort, on which so many writers are engaged, and in some instances the doctrines advanced seem to us to be distinctly heterodox, or, at least, not such as are accepted by the most approved authorities. This is recognized by the editor, who refuses, in the preface, to be held answerable for the views advanced by the individual authors, limiting his responsibility to the selection of the writers. However, the articles are all readable and suggestive, and, with the reservations which every one must make in his reading, the work may be accepted as a satisfactory exponent of modern gynæcological teachings.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON GENERAL SURGERY.

Stated Meeting, January 11, 1897.

B. FARQUHAR CURTIS, M.D., CHAIRMAN.

Removal from Fourth Cervical Vertebra of Bullet Located by X-Ray.—DR. A. M. PHELPS showed an *x*-ray photograph and a bullet from a case of gunshot injury. The bullet, fired from a revolver, 38-calibre, struck the thyroid cartilage, passed through the neck and lodged at an unknown point. There was pain in one shoulder and down the back, and the opinion of some who saw the patient was that the bullet had glanced downward and lodged at a point lower than the entrance. An *x*-ray photograph taken by one party failed to reveal the bullet, but that taken by another photographer was more successful, showing a darker spot in the fourth cervical vertebra. Through a nearly closed wound the Girdner electric probe was introduced and verified the position of the bullet. The ball had struck the hard lamina of the vertebra and flattened, and had barely penetrated the canal. The fourth cervical nerve had been injured, but the numerous blood-vessels and nerves at this level in the neck had escaped. Recovery after removal of the bullet was uneventful; the patient was discharged on the tenth day.

Bullets in the Brain Revealed by X-Ray.—DR. WILLY MEYER presented a patient whose case he intended to report more fully on another occasion. The young man had attempted suicide by shooting himself in the right temporal region. He was taken to a hospital, where he was trephined and the depressed bone was raised. Motor symptoms manifested themselves in the left arm and leg, pointing to an injury of the motor area in the right hemisphere. Dr. Meyer saw him and attempted to have *x*-ray photographs taken, and succeeded, by using both side and front exposure, in revealing three spots on a line with one another, one of them on the left side of the brain, two of them supposed to be a divided bullet or two bullets, and the third a splinter of bone. Possibly the third was also lead. Their removal was regarded as impracticable and nothing further was done. An interesting feature in the case was the falling out of the hair on the left posterior fourth of the head as a result of exposure to the *x*-ray.

Femoral Hernia in Woman Aged Sixty-seven, Strangulated One Hundred and Five Hours; Operation, Recovery.—DR. JOHN B. WALKER presented the patient. The history will be published subsequently.

Resection of Knee.—DR. A. M. PHELPS presented a girl, thirteen years old, whom he had treated mechanically for knee-joint disease a year and a half with the assistance of her family physician, and then, as the disease progressed and the *x*-ray showed the joint broken down, he performed resection. The case illustrated two or more points in connection with progressive knee-joint disease: 1. That the operation could be done rapidly, in this instance requiring thirteen minutes; 2, that, thorough removal of the diseased tissue having been effected, the line of division of bones being made convex and concave, so that one fitted into the other, and then a plaster splint applied so as to allow drainage, the limb could be perfectly immobilized in a straight line, union would take place, and the patient could leave the hospital in six weeks. Fenwick's V-shaped incision could be used if the other failed, and thus lock the end of the femur to the end of the tibia. He had excised the knee in seventy-one cases, with no deaths; average duration of operation, fourteen and a half minutes. In the case presented, as in some others, a sinus had been present, extending up from the knee, which he ripped up and cleansed out.

DR. J. P. FISKE and DR. PHELPS also presented cases in illustration of papers read later.

Discussion on the several cases being in order, DR. CURTIS expressed the opinion that the electric probe must have been of considerable assistance in locating the bullet in Dr. Phelps' case, in addition to the *x*-ray photograph, since the latter appeared somewhat obscure. He had himself repeatedly turned up the needle in the flap in cases in which the *x*-ray had led him to suppose it lay deeper and to make a deeper incision.

DR. JOHN GIRDNER said there was no question but that the *x*-ray was of assistance in locating the bullet in some cases. The cases in which it had appeared to him most useful were those of old gunshot wound in which the tract had closed and prevented use of the electric probe. In other cases the probe alone was often sufficient, and was an aid even when the *x*-ray had located the foreign body more or less plainly. But the latter was not applicable on the battle-field, and he understood that in Dr. Meyer's case he was unable to say whether one piece was bone or lead. The probe would decide that point. The latter was not so valuable in locating such objects as needles. He was awaiting reports of the use of the probe in the war between Japan and China, and also in the war in Cuba, where, he was informed, it had proven of service under the command of Maceo, as he had been informed by letter from Maceo himself. Bullets penetrating the skull not infrequently divided into two, and sometimes into many pieces.

DRS. WHITMAN and MILLIKEN thought there would be some tendency to knock-knee in Dr. Phelps' case of resection, and they queried whether this would have occurred if more time had been given to the operation.

The Ambulatory Treatment of Fractures of the Leg.—DR. JAMES P. FISKE read a paper on the ambulatory treatment of fractures of the leg, with a consideration of some of their complications, and with illustrative cases. Since the discussion of the subject at Berlin, 1894, considerable interest had been awakened in the ambulatory treatment of fractures of the lower limb. The method of which he should speak had been in use for many years in Roosevelt Hospital, where it was introduced by Dr. John Woodbury. It possessed certain new principles. After the bones were in place, a plaster splint was applied from the toe to near the knee and the patient was allowed to walk upon the limb from the second or even the first day in some instances, but in a few was kept abed ten days. There was no padding beneath the splint, nothing but a roller bandage. Some starch was added to one of the three layers of plaster bandage, to give slight elasticity. The foot was at a right angle to the leg. Thus applied, the upper part of the cast supported the greater part of the weight of the body. While in some instances the patient was allowed to walk at once, the rule was to keep him in the horizontal position for twenty-four hours, and if at the end of that time there was no pain he was directed to walk. The same rule applied to compound fractures if there was no infection. The cast was renewed if it weakened. While time was not gained for bony union, yet the patient was up and attending to his duties, and the after-treatment was shorter. The average time of wearing the cast had been twenty-eight days, but in a few cases it had been six weeks. During the treatment the general condition of the patient was main-

tained, which was an important point. In fracture of the fibula one hundred and ten cases had been treated by the ambulatory method at Roosevelt, and in eighty-one the splint was applied from the first; also a large number of cases of fracture of the tibia, and in fourteen cases of fracture of both bones—tibia and fibula. A fact which spoke favorably for the result was that in no instance had there been a lawsuit. One of two patients presented, a man, had sustained a Potts' fracture in a fall a week ago. The leg was put up in a plaster splint next day; the following day he was instructed to walk about, and had been going about since. Dr. Fiske repeated again that no pad was put under the bandage. The second case was of a similar fracture. The splint was applied, and the patient walked about almost from the first. The ambulatory treatment was first introduced at the hospital to relieve the crowded wards and also to enable patients to go about their work.

Dr. John Woodbury opened the discussion. He said the ambulatory method was introduced through necessity. They had to put the poor man in a splint which would enable him to go about; also that vacancies might be made for new patients. The method had been under observation at Roosevelt for ten years, and in some form had been employed more or less before that at Bellevue under Dr. Wood. It was under the guidance of Dr. Sands that he had been enabled to carry it out at Roosevelt. The patient was given a solid limb in from six to eight weeks. In no instance had one returned with a serious deformity which required correction. The splint allowed of no motion in the fragments while the patient was walking about. Proper hygiene was permitted. There was less danger of alcoholic delirium under this treatment than under that of rest in bed.

Dr. Johnson said he had seen many of the cases treated by this method at Roosevelt since 1888, and could testify to its value. He had not had occasion to regret its employment in a single instance. It did not give entire assurance against the development of delirium tremens in alcoholism, for he had seen this occur.

Dr. Willy Meyer said his attention had been directed to the method at the discussion in Berlin, and he had employed it in some cases with satisfaction since. It enabled the business man to go to his office. In the beginning he was afraid of medico-legal complications, and deemed it wise to let the patient choose between the old method of rest in bed and the ambulatory method. He understood the latter was being used also in fractures of the femur, including fractures of the neck in old people, whose hygienic condition was thus better maintained. The danger of hypostatic pneumonia which existed during long confinement in bed was also avoided.

Dr. Howard Lilienthal spoke favorably of the method which he had employed in a few cases. He raised the heel by plaster bandage to avoid the limp.

Dr. George Woolsey viewed the ambulatory method from two standpoints, namely, that of the hospital and that of the patient. It was useful for the purpose of clearing out the wards. On the patient's side it was indicated for hygienic reasons and to enable him to attend to certain duties. But while it would permit a man to go down town to business, it would not enable the hodcarrier to ascend the ladder for five or six weeks at least. Therefore we might yet strive for some better treatment, especially since there was considerable stiffness in the limb when finally the plaster splint was discarded. He had employed the massage and ambulatory treatment with considerable satisfaction—the patient going about on a cane. He understood the massage treatment was recently being combined with the use of the plaster splint, massage being used when the splint was removed and the patient going about with the splint applied. The advantage was avoidance of deformity.

Dr. A. M. Phelps believed that in oblique fractures the ambulatory treatment with plaster splint would permit the bones to slip past each other and cause some shortening. This objection need not apply in transverse and serrated fractures. Following the practice of Dr. John Swinburn, he allowed the patient to go about on crutches, with the fractured limb done up in a form of hip-joint splint, traction being exerted to keep the fragments apart and splint and leg being put in plaster.

Dr. Fiske closed. He thought shortening might result if the splint were to break or spread, but he had not seen either accident happen. If it became loose or limber, he removed it and applied another. As stated before, in some cases the patient was not allowed to walk for ten days. Gross had suggested ambulatory treatment as long ago as twenty years.

Bone Grafting for Ununited Fractures.—Dr. A. M. Phelps read the second paper and presented an illustrative case. Among the causes of ununited fracture were lack of nutrition, foreign bodies between the fragments of bone, bad coaptation, and sclerosis. Different methods had been resorted to with more or less success for inducing union. Thomas, of Liverpool, had suggested hammering the fracture with a mallet, then putting the limb up in plaster and allowing the patient to walk, thus grinding the ends of the bone together. Senn had suggested putting in decalcified chips of bone between the ends of the fractured bone. Another method was to turn in periosteum and pin the bones. In the cases which he had to report in his paper, eleven in number, one or more of these methods had been tried unsuccessfully before he had attempted bone grafting. His first attempt at bone grafting, different from that which he now practised, occurred about 1890, at one of the city hospitals, and was the source of a good deal of newspaper notoriety. A portion of the forearm of a dog, still retaining its nutrient attachment to the dog, was grafted into the ununited bones of a child's limb, and the two were bound together with plaster. But the dog became restless, squirmed in its plaster jacket, and it was necessary to separate it about the tenth day. The graft did not unite. He then adopted the plan which had succeeded in the patient presented and in several others. It consisted in taking numerous chips of the forearm of a dog, preferably a pup, and grafting them into longitudinal splits of the periosteum covering the ends of the bone which had just been cut down upon and wired together. The chips of bone started centres of ossification which resulted in good bony union. They seemed to act not unlike skin grafts on the surface of the body. In the case of the young woman presented, who had had ununited fracture of the bones of the forearm, he had employed about fifty bone grafts. Subsequently about a dozen of them came to the surface and were removed, but the remainder "took." There was slight shortening of that arm, but its use and power seemed normal. In one of the successful cases the bone grafts into the arm were obtained from the knee of another patient, on whom he was doing excision. In the case of a man who had no use for his little toes because of the presence of corns, he utilized these for bone grafts into his ununited fracture. Out of the eleven cases two came to amputation, one resulted in fibro-osseous union, in eight there was perfect bony union. All were of the extremities, five of the leg. There were successes, there were failures. He gave the method for what it was worth. When other methods failed, he thought this one of bone grafting should be tried before resorting to amputation.

Dr. Phelps had given up silver wire for uniting the bones. It was too fragile. He used strong steel wire and attached it to screws put into the bones.

Dr. Curtis asked whether the grafts of bone themselves grew, or whether they simply stimulated growth from the ends of the bones and then disappeared, as seemed from microscopical examination to be the case when blood clot filled the intervening space. In the case of ununited fracture of the tibia he suggested that the gap might be filled by dividing and pushing in the fibula, and thus avoiding much shortening of the limb. He had used decalcified bone in a case of ununited fracture of the femur without success, and subsequently amputated.

Dr. Willy Meyer suggested the use of the method of Bardenheuer, turning a piece of the same bone with periosteal and muscle attachments over into the gap, as one would slide or transplant skin to fill a surface gap.

Officers.—Dr. Curtis declined a renomination as chairman. Dr. W. W. Van Arsdale was elected *Chairman*, and Dr. John B. Walker was re-elected *Secretary*.

SECTION ON GENERAL MEDICINE.

Stated Meeting, January 19, 1897.

R. W. Wilcox, M.D., Chairman.

The Serum Diagnosis of Typhoid Fever.—Dr. William H. Park read a paper on the serum diagnosis of typhoid fever and made microscopical demonstrations. After a brief review of the work of Pfeiffer, Widal, and some others, in the course of which he described what constituted the serum method of diagnosis in typhoid fever, the author passed to the analysis of the observations made by the health department since a few months ago. To state the method briefly, if one added to a culture of the typhoid bacillus an equal amount or even a fractional amount up to 1 to 10 or 1 to 100 of the blood serum of a patient who had typhoid fever or had recently recovered from that disease, the typhoid bacilli would cease to move about freely and singly in the fluid; their action would become inhibited according to the proportion of the serum added; then they would become agglutinated into groups with intervals of no bacteria; lastly, some of them would become deformed and break down. The three stages of the change were inhibition, agglutination, dissolution of the typhoid bacilli. As the bacilli became agglutinated into groups, they settled to the bottom of the fluid. Microscopical examination showed them in clumps on the slide. In marked cases there was instantaneous reaction on adding the serum to the culture. Instead of using the serum of the blood of the suspected subject, because of the difficulty of obtaining it, the board of health at first had given instructions for sending to the depots of the department, located at pharmacies throughout the city, dried blood which at the laboratory was diluted with water and made fluid. There should be at least two or three drops of the dried blood. While the dried blood had advantages, it also had disadvantages, one of them being that it required to be mixed with at least six times its amount of water, and then, when an equal amount of the culture was added, it made a dilution of 1 to 12. When one had serum he could use an amount equal to that of the culture, and it could be measured out more exactly and constitute a quantitative test. It being difficult to draw a sufficient amount of blood from which to obtain the serum, it was best to make use of a small flying blister. But the dried blood answered the purpose well enough in most cases. It was necessary, however, to get a reaction within fifteen or twenty minutes to be assured that it was due to typhoid, for if none occurred until after that period the appearance might be due to a pseudo-reaction by the bacilli becoming entangled in fibrin. Even with serum a quick reaction was more reliable, although a late one was less likely to deceive the examiner, since in serum fibrous clumps were absent. If the reaction were late, it was best to make a subsequent examination.

Before giving the results obtained by the health department, Dr. Park presented a table of results obtained by Widal, Achard, Haushalter, Gatrin, Grünbaum, Durham, Delepine, Greene, and Johnston, amounting in all to about 422 cases of possible typhoid fever. Most of these observers had obtained pretty uniformly successful results. Out of the 422 cases of supposed typhoid a positive result in accord with the clinical history was obtained in 312. In only 12 cases was the result wrong or apparently misleading.

In the laboratory of the health department of this city they had employed the serum method of diagnosis of typhoid fever in 350 cases of possible typhoid. In about 130 of these cases, as far as they could learn, the histories had been that of typhoid. In 101 of the 130 the reaction was obtained; in 30 it had not been obtained. In reference to the period of the disease at which the examination was made, in the first week there had been 70 per cent. of positive results; in the second week, 69 per cent.; in the third week, 75 per cent.; in the fourth week, 92 per cent. In no case having clear clinical typhoid history had there been throughout the entire course of the disease no reaction whatever, either by the dried blood or serum method.

As to whether other cases than typhoid would give the reaction, in 104 cases 92 gave no reaction. No healthy person's blood had given any reaction with a dilution of 1 to 10. In three colored people, one having pneumonia, one Bright's disease, and the third gangrene of the foot, there was a reaction with 1 to 10; but Dr. Park had doubt whether some typhoid infection might not have been present in these cases. They were the only ones which had given a reaction in a dilution above 1 to 10 among numerous cases without typhoid which had been submitted to the test. As to the duration of the reaction in typhoid, in some cases it had disappeared a week or ten days after recovery from the disease, but usually it remained from six to nine months, and very rarely two years. An attack of typhoid prior to one year could be excluded as the cause of the reaction. Dr. Park was of opinion, formed from studies thus far carried on, that if serum were used, and the reaction appeared with a dilution of 1 to 50, the case could be positively pronounced typhoid; if the reaction were present with a dilution of 1 to 25, about one per cent. of such cases would not be typhoid. The possibility of the disease not being typhoid when the reaction was obtained was somewhat greater the greater the quantity of serum required in proportion to the culture fluid. He thought this method would be of special value in distinguishing among cases hitherto classed doubtfully as malaria and typhoid. In one case the reaction was absent when blood drawn from the spleen proved the diagnosis of typhoid.

Dr. John W. Brannan opened the discussion. The reaction agent, whatever it was, evidently lay not in the fluid elements of the blood, for dried blood diluted with water was sufficient to produce the reaction. In some respects dried blood was preferable, especially if it was desired to retain it for subsequent use. It gave the reaction some time after the kept fluid blood or serum had lost that power. According to his observation the reaction diminished rapidly after the attack of typhoid, so that blood drawn six months afterward seldom gave any reaction. Most writers in this country had said that any practitioner could make the test for himself. But such a test could not be very reliable, since one with the experience of Dr. Park had found

the result doubtful in about one out of five cases. Dr. Brannan said that while the exact clinical value of the method had not yet been determined, he was of opinion that in about ninety-five per cent. of cases of typhoid the reaction would be obtained some time within the ninth day; and perhaps one case in one or two hundred of those not typhoid would give it. The fact that all three of the cases not typhoid, or supposed not to be typhoid, in which the health department had obtained the reaction, occurred in colored people, pointed rather to the view which some inquiry made by him seemed to confirm, that colored people possessed a certain degree of immunity to typhoid and had the elements in their blood to which the reaction commonly present only after typhoid was due.

Dr. H. M. Biggs said it had been the policy of the health department to extend its assistance in the diagnosis of infectious diseases as rapidly as possible, because of their danger to the public health. When the work of Widal and Pfeiffer became known, it was decided to try the method in the manner already mentioned. It seemed to him that Dr. Park's estimate of the value of the method was sufficiently conservative. Its value, he thought, would become even greater with experience. He quite agreed with Dr. Brannan, that to be of much value the test would have to be made by an experienced bacteriologist. It could not be made at the bedside by everybody, as had once been stated by Widal. In the opinion of the speaker, many cases not giving the typical clinical history of typhoid, but giving the reaction, would be found to be real typhoid. There was no reason to believe that typhus would give the reaction any more than other diseases besides typhoid, and if this were true he thought the test would be of decided aid to the sanitary department, which not infrequently encountered cases which presented many of the clinical features of typhus, when in reality they were typhoid.

Dr. Lambert, in considering the nature of the agglutinative substance, said it was not the bactericidal substance, and it was present in all of the serous fluids of the body when not secreted very rapidly. He thought this method of diagnosis was of value, but the difficulty with physicians was that they looked for an infallible test. In making a diagnosis from the clinical picture, they were compelled to be less exacting in their demands.

Thankful for Any Aid in Diagnosis.—Dr. F. W. Jackson thought all physicians were willing to reach out for any aid in diagnosis in a disease which presented so varied a clinical picture as did typhoid fever in New York. He could not say, however, that the test under discussion had been of much aid to him in diagnosis since he had resorted to it in September. The trouble had been that in the very cases in which its aid was most needed, those with a doubtful clinical diagnosis, the bacteriologist's report had been that the reaction was uncertain. Then there were the two cases (from Bellevue Hospital) in which the health department had returned a report of positive reaction when typhoid did not exist. Further, there was the typical case of typhoid fever in which the reaction was negative. In two other cases of typhoid the test became positive only after the patients had got out of bed. He wanted a diagnosis early in the disease, not after its cure. We should not praise the method too highly until its limitations had been defined. The Widal test was at present simply one of the aids in diagnosis of typhoid fever.

Dr. J. S. Thatcher said that at the Presbyterian Hospital they had employed the test in about one hundred cases. In only two cases of typhoid fever had they utterly failed to get any reaction after making repeated examinations. In one case the reaction appeared nicely, and at autopsy the following day no evidence was found of typhoid. Dr. Thatcher thought the test a valuable one in diagnosis of continued fever of uncertain nature.

Dr. Egbert Le Fevre had employed the method since November in 173 cases of different diseases. Clinically there were out of the 173 cases 15 of undoubted typhoid. These showed the typical reaction. In only 2 of the 15 was there at any time doubt about the clinical diagnosis. In one the symptoms were much like those of typhus fever; the blood tests were negative until the sixth day, when the reaction became typical. In this instance the value of repeated examinations was shown. Of the remaining 159 cases there were 9 of febrile disease which could not be classified after a week's observation. In only 3 cases not typhoid from among the 159 was the reaction obtained. One was a case of pneumonia; reaction absent the first day, present on the second day and after that until the eleventh, when it disappeared. This was a white man. The second case was one of cancer of the stomach; typical reaction; no history of typhoid. The third case was one of cardiac disease; reaction pretty clear. Dr. Le Fevre hoped that by the Widal test, the test for plasmodium of malaria, and other tests, we would finally become able definitely to classify certain fevers in which at present the diagnosis often remained uncertain.

Dr. Ellsberg had followed up about twenty cases of typhoid fever with daily observations at Mt. Sinai Hospital. He thought the test would come to be definite, but at present we ought not to be too positive. In the hospital they had obtained the reaction as early as the fourth and fifth day, but in the great majority of cases it was not obtained until from the eighth to the twelfth day. In one it was absent until the twenty-sixth day, in one until the twenty-eighth, and in one it had not yet appeared, the thirty-fifth day. It had not been obtained there in any case not typhoid. He thought it was an excellent method for distinguishing between the colon and the typhoid bacillus. In one case of external sore, typhoid not being suspected, the reaction was present; next day it was absent, and it did not return until the fourth day, then continued to be present. The patient did not begin to show symptoms of typhoid until two or more days after the first reaction. The speaker was unable to explain such a case.

Dr. Park closed. He suggested as an explanation of Dr. Ellsberg's case that there might at first have been a local typhoid infection; reaction showed itself, disappeared; then regular typhoid infection developed and the reaction became continuously present. He felt that in this test we had something of marked diagnostic value, although it was yet in the experimental stage.

By request of Dr. Bulkley, made because of the lateness of the hour, the reading of his paper, "Some General Considerations in Connection with Diseases of the Skin," was postponed until the next meeting.

Officers.—Dr. Wilcox declined a renomination as chairman, and on motion of Dr. Robinson he was authorized to appoint a chairman for the ensuing year. Dr. Wilcox appointed the secretary, Dr. L. F. Bishop, as chairman. The section then elected Dr. William N. Hubbard secretary.

Progressive Polyarthritis Deformans attacks both old and young. The only medicines which prove effectual are iodine and the iodides combined with arsenic, and taken in the middle of the two principal meals. The arsenical treatment may alternate with tincture of iodine (four to ten) drops in wine, sweetened water, or orange syrup. For the iodine the iodides of potassium and sodium in suitable dose may be substituted.—*Rev. Internat. de Méd. et de Chir.*

THE NEW YORK PATHOLOGICAL SOCIETY.

Stated Meeting, November 11, 1896.

JOHN SLADE ELY, M.D., PRESIDENT.

Tuberculosis.—DR. ROWLAND G. FREEMAN presented specimens from a colored child, three years and a half old, who died at the New York Foundling Asylum on April 25, 1896. A short time previously the child had had measles and pneumonia. There had been scattered râles over the chest, the spleen could be felt, and there was one enlarged lymph node on the right side of the neck. The clinical diagnosis had been tuberculosis. The autopsy had been performed immediately after death, and on opening the thorax a large mass of tumors had been found in the anterior mediastinum, and also a line of enlarged lymph nodes on the upper surface of the diaphragm. The largest ones were two inches in diameter. In some places they were hard; in others, there was miliary infiltration. The lungs were bound down by adhesions, and contained a very moderate amount of tuberculous infiltration. The bronchial nodes were much enlarged, and of the same character as those in the anterior mediastinum and along the diaphragm. The omentum showed very beautiful miliary tubercles. The capsule of the liver was studded with white tubercles, about one-sixteenth of an inch in diameter. The spleen showed the same appearance on the surface. The kidneys were pale. The mesenteric nodes just below the liver were enlarged. Adjacent to the caput coli was a node, one-half inch in diameter, and over this the mucous membrane presented an ulcer, about one-fourth of an inch in diameter. It was probable that this was the origin of the infection.

DR. HENRY POWER said that the case presented had suggested the question as to whether the tubercle bacilli could pass through the stomach without being destroyed. It seemed to him that they would not necessarily be destroyed, on account of the protection afforded by the mucus.

DR. FREEMAN said that he thought there was exceedingly good authority for believing that the tubercle bacilli were not destroyed in the stomach. Experiments had been made in this direction with artificial gastric juice, and also on animals; and these indicated that the bacilli were not destroyed. He had presented quite a similar specimen to the pædiatric section of the Academy of Medicine last spring.

DR. WILLIAM VISSMAN did not think that tubercle bacilli could pass through the perfectly healthy stomach and retain their vitality; however, as the stomach was rarely entirely healthy, it was probable that the tubercle bacilli often passed through safely. An argument in favor of this view was the occurrence of more extensive lesions above than below the stomach. He recalled the case of a young lady, a member of a markedly phthisical family, in whom both tuberculous peritonitis and enteritis occurred, yet there was no cough.

THE PRESIDENT thought there could be little question that tubercle bacilli often passed the stomach in a perfectly viable condition. This bacillus was known to be rather resistant to external influence, such as drying, and the slight exposure to the acid gastric juice would hardly seem sufficient to kill it. Tuberculosis had been very frequently produced experimentally by feeding animals with the tubercle bacilli. Again, as Dr. Vissman had said, the stomach in consumptives was frequently deranged and the degree of acidity lessened. He found it rather hard to believe that the very small ulcer in the caput coli, in the case presented, was the point of entrance of the large number of tubercle bacilli that must have been disseminated through this child's body in order to produce such extensive lesions in the glands. The ulcer appeared insignificant, there was but little infiltration in the wall of the intestine about it, and he was inclined to think that the ulceration was of recent development, quite possibly as a result of the extension of the process from the lymph nodes. He did not mean to say, however, that the case was not one of intestinal infection, for the evidence pointed strongly to such an origin; yet he felt that the bacilli were so generally inhaled in cases of tuberculosis in which the bronchial lymph nodes were so much enlarged that it was not at all unlikely that in this case both modes of infection had been in use.

DR. FREEMAN said that in tuberculosis the main lesion was often found at a considerable distance from the point of entrance. Thus, in tuberculous meningitis, a very considerable meningitis might be present, and yet no other marked lesion elsewhere could be detected.

General Tuberculosis.—DR. F. M. JEFFRIES presented specimens from a case. The patient was forty-four years of age, and died two days ago. There were small nodules over the pericardium. The pleural cavity was entirely obliterated, and the pleura contained small tubercles. In the liver were to be found here and there very small nodules, apparently tuberculous, but difficult of detection.

Dr. Jeffries also exhibited the lungs from another case of tuberculosis. In the upper lobes were cavities, and nodules were scattered throughout the organ. No clinical diagnosis of tuberculosis had been made, notwithstanding the advanced stage of the disease.

Dr. Jeffries also presented specimens taken from a woman who had been for two days in the alcoholic wards at Bellevue Hospital. On admission her temperature had been 100° F., but it had gradually risen, until just before death it had reached 104 F. No complete physical examination had been made. The autopsy showed marked general tuberculosis. The peritoneum was studded with tubercles; the diaphragm was adherent to the liver; the liver was enlarged and fatty; the kidneys showed tubercles, both in the cortex and in the pyramids. The suprarenal bodies were apparently not affected. All of the glands around the pancreas were greatly enlarged and apparently cheesy. The lungs were the seat of what appeared to be acute tuberculosis. There were a few tubercles in the spleen.

Photomicrographs of Bacteria.—DR. HENRY POWER exhibited a photomicrograph taken with an amplification of twenty-five hundred diameters, and showing the absence of the usual halo. He said that in looking at bacteria with a very high power, it was often difficult to determine whether or not a capsule was really present. This appearance, he believed, was due to a particular mode of illumination. His theory was that the appearance was produced by the bacteria having a high refractive index and acting as a lens. Acting upon this theory, he had used Dr. Piffard's new mounting-medium, and had found that this lens action had been destroyed and the difficulty alluded to had been completely obviated.

Tuberculosis of the Gum.—DR. J. S. ELY presented six microscopical specimens of tuberculosis of the gums. He said that this condition was rather an unusual one, or, at least, was not often recognized. The material from which the specimens had been prepared had been sent to him by Dr. R. H. M. Dawbarn for examination. The lesion had occurred in a young man, who had been apparently perfectly healthy, with the exception of a slight ulceration in the mouth on the side opposite to that at which the lesion had developed later. The ulceration had been treated with dilute acid. A portion of the tissue had been submitted to him for microscopical examination, and he had

found unmistakable evidence of tuberculosis. Dr. Dawbarn had since incised and scraped the part thoroughly, and the report was that at the present time the parts were apparently healing. Dr. Ely said that he had been able to find only one case of tuberculosis of the gum on record, and this had been reported by a Swede, in 1884. The case had been reviewed in Virchow's *Jahresbericht*. The patient, who was forty years of age, had severe pain in the mouth and radiating toward the left ear. On examination, an ulcer with undermined edges was found behind the lower left wisdom tooth and extending to the fauces, and later on to the soft palate. The base bled readily. At the same time small grayish nodules were found scattered over the pillars of the fauces and over the soft palate, when the nodules subsequently increased in size and finally became confluent ulcers. The microscopical examination had left no doubt whatever as to the tuberculous nature of the growth, and tubercle bacilli had also been found in the tissues and in a cavity of a wisdom tooth which was extracted. The patient ultimately died of his tuberculosis.

Dr. Ely said that this case had led him to study the subject of tuberculosis of the mouth, and he had been able to find but few cases on record. Attention had been first called to this condition by Ricord, prior to 1872. In 1872 a case of three tuberculous ulcers on the right edge of the tongue was reported by Reverdin, in a man, forty-six years of age, suffering from phthisis. In 1883 two cases had been reported. In one of these there was an ulcer of the lower lip, and in the other an ulcer of the tongue. Tubercle bacilli were found in both cases. There was also on record a case of "tuberculous angina," occurring in a phthisical patient, in which there were grayish ulcerating patches on the anterior pillars of the fauces and soft palate. The ulcers had undermined and indurated edges, and microscopical examination proved them to be tuberculous. He had found on record a case of lupus of the pharynx; and in 1887, at the Heidelberg clinic, twelve cases had been reported of lesions in different parts of the mouth, but principally upon the tongue and lips. In two of the cases, the lesion in the mouth was the only tuberculous lesion that could be detected; so that undoubtedly a lesion might exist as a purely local one, and be amenable to treatment. In about half of his cases he had succeeded in healing the ulcers. In 1887 Dr. Delavan had reported a case of tuberculosis of the tongue; and, later, Dr. Bull had published a report of the surgical treatment of that case by amputation of the tongue. There had been no recurrence in this instance.

Dr. W. H. Park remarked that in a large dispensary practice in throat diseases he had not come across a single case of tuberculosis of the gum. Such lesions in the pharynx were, however, fairly frequent.

Dr. Ely said that in studying the literature of the subject he had observed that the salivary glands seemed to be quite frequently affected.

Extra-Uterine Pregnancy.—Dr. F. M. Jeffries exhibited a specimen. He said that on examination nothing had been found but bloody fluid, the fœtus having been macerated, but sections from the walls showed placental tissue.

Atrophy of Left Lobe of the Liver.—Dr. Jeffries also exhibited a liver, showing almost complete atrophy of the left lobe. The liver had been removed from a man of forty years. There were no other features of interest at the autopsy.

Rupture of Aneurism into Pericardium. — Dr. Jeffries then presented specimens from a case of sudden death, due to hemorrhage into the pericardial sac from the rupture of a small aneurism of the arch of the aorta.

Dr. Martha Wollstein reported that examination of the specimens presented by her at the last meeting showed them to be non-tuberculous, and that the case was one of ordinary chronic cystitis with an ascending nephritis.

The society then went into executive session.

MEDICAL SOCIETY OF THE STATE OF NEW YORK.

Ninety-First Annual Meeting, Held at Albany, January 26, 27, and 28, 1897.

James D. Spencer, M.D., of Watertown, President.

Thursday, January 28th—concluded.

The report of the nominating committee was read by Dr. Eugene Beach and confirmed by the society.

Would Abolish the Nominating Committee.—Dr. William James Morton, of New York, before offering an amendment to the bylaws, said he desired to add his hearty congratulations on the election of the new president. He had been interested in hearing the results of this election. After considerable experience in life, he thought he had not seen a sadder spectacle than that of the members of this great and honored society led up like sheep to the shamble and slaughtered at the dictates of machine politics. He offered as an amendment to the bylaws that hereafter the nominaton and election of officers, etc., take place at the end of the third day's session in open meeting.

The President ruled that under the bylaws this proposed amendment would have to go to the committee on bylaws. While he thought it was not strictly in order, several members made some remarks, among them Drs. Macdonald, Bendell, Beach, and others, in opposition to the amendment.

Place of Meeting.—Dr. O. F. Kinloch offered the following amendment to the bylaws: "The annual meetings of this society shall be held alternately in the cities of Albany, New York, and Buffalo." It was referred to the committee on bylaws.

Members of the Nominating Committee Must Not Nominate Themselves.— Dr. Hermann Bendell offered as an amendment to the bylaws that members of the nominating committee shall not be allowed to nominate one of their own number for officer or delegate. It was referred according to the rules.

For Information of Legislators.—Dr. F. C. Curtis called attention to the statement of Senator Brush at the annual dinner, that he had introduced a bill into the legislature to provide for the appointment of a commission to investigate the water supply for New York, Brooklyn, and the Hudson Valley cities. In view of this fact, he moved that the society purchase and distribute to the legislators a copy of the journal containing all of the papers read Wednesday on the pollution of water. Carried.

The Management of Club Foot. — Dr. A. M. Phelps, of New York, gave a brief outline of a paper on this subject on Wednesday. It was not until the fourth year of age that the cuneiform bones became ossified. Prior to that age the foot could be readily moulded into correct position, and the earlier the treatment was begun after birth the better. That treatment consisted in manipulation, carrying the foot with the aid of the hand as nearly around into position as possible, then fixing it with adhesive plaster, removing this next day, and repeating the treatment every succeeding day until the foot had been placed in a position of overcorrection. This could be effected by the third month, but the treatment must not be relaxed as long as there was any tendency to deformity.

If this method did not succeed, he divided subcutaneously the soft parts which offered opposition, but never went farther with cutting operations than was necessary. It was seldom that bones had to be cut or broken.

The Necessity of New Methods of Early Diagnosis in Tuberculous Disease for Curative Treatment.—Dr. J. B. Ransom, of Dannemora, in this paper, pointed out the fact that tuberculosis, while regarded by the public and many of the medical profession as a hopeless disease, was very amenable to treatment when this was instituted early. There was great need of new methods of early diagnosis, but he only desired to make clearer the advantages to be gained meanwhile by an intelligent application of such diagnostic methods as were well known to the profession in cases of cough and such symptoms as pointed to possible tuberculosis before auscultatory and percussion signs pointed to advanced changes. Tuberculin, which was so successful as a diagnostic means in cattle, was not considered safe in man. The great prevalence of tuberculosis in the State prisons was pointed out. Sunshine and dry air were exceedingly important in treatment and prevention.

Dr. E. F. Brush took exception to the assumption by the author and the medical profession generally that the tuberculin test was uniformly accepted by veterinarians as reliable.

Dr. Thornbury said he had looked upon the tuberculin test as absolute in cattle, and Simon, who was of the highest authority, had said it was reliable in ninety-nine out of one hundred cases.

Drs. Macdonald and F. C. Curtis made a few remarks.

Hernia of a Sarcomatous Ovary.—Dr. George Seymour, of Utica, read the history of a case which had come under his treatment, of inguinal hernia in a woman, forty-eight years of age, the tumor having first been noticed two years before. It had not been reduced for a year. On operating he found the tumor, in the inguinal canal and adherent to the round ligament, to be the ovary. It weighed five ounces, and was the seat of spindle-celled sarcomatous degeneration. It was removed and with it a considerable length of pedicle. Dr. Seymour had found this a rare condition, as far as he could learn from book reference.

Dr. Willis Macdonald had seen only one case in which a hernial sac contained an ovary. It was not sarcomatous.

On motion of Dr. Bendell, the president, Dr. Spencer, was tendered a vote of thanks. The society adjourned.

Diet in Bright's Disease.—It is agreed that the most rational diet is a mixed one. The estimate commonly given is that meat should constitute one-fourth and vegetable food three-fourths. This is often overstepped, and the proportion brought to two to four. Such indulgence throws into the circulation a large amount of nitrogenous waste, which it is the office of the kidneys to remove from the system. An increased amount of organic excretives, continually demanding removal, throws a considerable tax upon these organs, which is frequently rendered more severe by a hyperacid concentrated condition of the urine, as these subjects seldom drink an adequate amount of water. This irritation, if long continued, eventually leads to functional and finally organic impairment of the kidneys. To these sources of irritation must be added the deleterious effects upon the renal structure of the excretion of the byproducts of faulty gastric and intestinal digestion, frequently present from the dyspepsia so common among those who overindulge at table. —Dr. Elliott, *North American Practitioner.*

Therapeutic Hints.

Bronchial Hemorrhage.—In presenting a summary of my own treatment of bronchial hemorrhage no claim is made to anything new; but simply that it is based upon a well-defined principle, has a definite object in view, and that the measures form a harmonious whole without contraindications. It includes: 1st, rest; 2d, morphine; 3d, aconite or other vascular sedative; 4th, dry salt and a saline cathartic; 5th, counter-irritation; 6th, obstructed expiration. It excludes: 1st, astringents; 2d, ice externally; 3d, stimulants; and 4th, the vasoconstrictors.—Dr. Charles E. Quimby, *Transactions of the American Climatological Association*, vol. xii., p. 111.

Phthisis.—Dr. Foxwell, of Birmingham, who has had considerable experience in the internal administration of iodoform, regards it as almost a specific for phthisis. He gives it in one-grain pills, six times a day, and finds that it gives better results than any other drug or combination of drugs with which he is acquainted. It soothes the nervous system of erethistic subjects; lessens cough and expectoration; powerfully stimulates nutrition, and markedly improves the condition of physical signs. One of his patients took fifty grains a day without inconvenience, and another took from twenty to thirty grains a day, for two years and a half, with no detectable ill effect. It would appear from these obervations that iodoform exerts as marked an influence on phthisis as mercury does on syphilis. Dr. Foxwell did not meet with the comatose condition described by other writers as the result of the employment of large doses. It would seem probable that, in these cases, the drug acts as a pure antiseptic, and not by virtue of the iodide of sodium into which it must be converted in the blood. I have employed the iodoform treatment in a large number of cases, both in phthisis and winter cough, and although, in the main, I confirm Foxwell's treatment, I have met with several cases in which the employment of large doses had to be abandoned on account of the nausea and vomiting resulting from the administration of the drug, and the powerful odor it imparted to the breath. Iodoform is conveniently made into pills with sugar of milk and glycerin of tragacanth.—*Manual of Materia Medica and Therapeutics*, by William Murrell, M.D., p. 254.

Treatment of Affections of the Intestines by Insufflations of Boric Acid.—*La Médecine Moderne*, March 14, 1896, gives the following curious procedure for treating constipation which Dr. Flatau, of Berlin, has recommended since 1890. Dr. Cramer who has experimented with this method is convinced that it is indicated especially in cases in which constipation is accompanied by flatulency. Dr. Flatau proceeded as follows: After careful cleansing of the anus, boric acid was applied to the mucous membrane on the rectum and its absorption was facilitated by means of friction. Later he decided to employ an insufflator, by the aid of which he caused the boric acid to penetrate, in the form of a powder, into the inferior portion of the rectum. Dr. Cramer has also adopted the use of the insufflator. Dr. Merkel has published two papers which bear witness in favor of this method of treating constipation. The technique is as follows: The buttocks of the patient are held apart by an assistant; the cover of the insufflator, greased along its whole length, is introduced into the rectum. Then a quick and energetic pressure is exerted on the rubber bulb of the instrument. From two to four grams of boric acid are thus introduced into the large intes-

tine. It is requisite that the canal have a sufficiently large lumen (one to ten millimetres in diameter) and that the rubber bulb have a corresponding dimension. The effect of the insufflation manifests itself at an interval of from five minutes to three hours. It rarely fails. In order to obtain a lasting result, the insufflations should be continued for from four to six weeks. This treatment has been particularly efficacious with patients (principally men) who complain of a sensation of fulness and weight in the abdomen.

Massage in Gynecology.—We read in *La Médecine Moderne*, March 14, 1896, that M. Ponomareff has employed massage for different troubles of the pelvic organs of women. This method is indicated in the following maladies: Imperfect involution of the uterus after labor and especially after miscarriage. In this class of cases massage rapidly diminished the size of the uterus. It prevents hemorrhage as well as the development of chronic troubles. 2. Chronic metritis, before it reaches the point of sclerosis, but accompanied with endometritis and dysmenorrhœa. 3. Defective position of the uterus and ovaries. Massage acts favorably in these cases on the uterus and its ligaments, and thus permits a correction of the defective position of the pelvic organs. 4. Perimetritis and chronic parametritis are favorably influenced by massage; the exudates are reabsorbed, the adhesions become more pliable and very often disappear. 5. Gynecological massage is of great diagnostic value, as for instance, when the demarcation is not very clear between the uterus and a benign tumor. By diminishing the congestion of the uterus, massage permits of a more precise diagnosis. The following are the cases in which gynecological massage is contraindicated. (*a*) Pregnancy (normal and extra-uterine). (*b*) Malignant tumors of the pelvic organs. (*c*) All the diseases accompanied by suppuration, tubal blennorrhagia, and blennorrhagic perisalpingitis. (*d*) Acute febrile affections. The manual operation employed by the author was very simple; the finger, placed in the vagina or rectum, remains fixed and holds the diseased organ in place. With the hand placed on the abdomen friction of the affected organ is executed across the abdominal wall, which ought to be relaxed as much as possible. The patient is placed in the dorsal decubitus, with the knees flexed. The *séances* should take place every day or every other day for a period of from five to ten minutes.

Keratin.—A substance prepared from animal horns by treatment with pepsin and ammonia. It is used for coating pills that are desired to pass into the intestine unchanged, so that the action may be localized. It is insoluble in the acid gastric juice, but soluble in the alkaline liquid of the intestine.—*The Prescribers' Pharmacopœia*, p. 196.

Nasal Insufflations in whooping-cough made five times daily with the following powder, reduce the number and intensity of attacks and bring about rapid cure:

℞ Benzoin (pulv.) ..... 10 parts.
Salicylate of bismuth ..... 10 "
Quinine sulphate ..... 2 "
—Moizard.

Thyroid Therapy.—Dr. J. B. Herrick (*Medicine*, August, 1896) thinks he is justified in announcing the following conclusions concerning thyroid extract: 1. It is curative in myxœdema (idiopathic, cretinism, operative). 2. Many cases of obesity are cured by it. 3. Simple hyperplastic struma, particularly in the young, is frequently cured or improved. 4. In these instances just named the remedy must be continued for an indefinite length of time to prevent relapse. 5. It may prove of value in some cases of tetany. 6. In skin diseases it is of doubtful value, also in mental and nervous diseases. 7. It is contraindicated in exophthalmic goitre. 8. The results are practically the same whether fresh glands, extracts, or dried glands are used. This may also be true of the thyro-iodine of Baumann.

Acute Sore Throat of Non-Diphtheritic Type.—Dr. Lyon in the *Revue de Thérapeutique Médico-Chirurgicale*, May 15, 1896, recommends small doses of one of the following preparations:

℞ Antipyrin ..... gr. xv.–xlv.
Water ..... ʒ iiiss.
Syrup ..... ʒ i.
S. A teaspoonful three times a day.

Or:

℞ Neutral sulphate of quinine ..... gr. vij.–xv.
Syrup ..... ʒ vi.
Syrup of codeine ..... ʒ vi.
Distilled water ..... ʒ iiiss.
S. Teaspoonful every three or four hours.

Dr. Lyon recommends a large dose of salol when there is a rheumatic taint. It is claimed that this will relieve pain, reduce temperature, and exert a general anæsthetic influence which is of value. When there is marked systematic disturbance, particularly with disorder of the digestive tract, benzo-naphthol and a tonic, such as cinchona or alcohol, may be given. As local treatment he recommends either a small piece of ice allowed to melt in the mouth or a gargle as follows:

℞ Boric acid ..... ʒ ss.
Hydrochlorate of cocaine ..... gr. vij.
Glycerin ..... ʒ iss
Water ..... ʒ i.

If the tonsils are inflamed use:

℞ Hydrochlorate of cocaine ..... gr. iv.
Menthol ..... gr. xv.
Olive oil ..... ʒ i.

Hot compresses may be applied to the throat. Dr. Lyon thinks the following gargles most useful:

℞ Salicylic acid ..... ʒ ss.–i.
Borax ..... ʒ ss.–i.
Honey ..... ʒ i.
Distilled water ..... ʒ viij.

Or:

℞ Borax ..... ʒ iiss.
Hot water ..... ʒ vi.
After solution:
Tincture of myrrh ..... ʒ i.
Syrup of mulberries ..... ʒ i.

Painting with equal parts of glycerin and guaiacol may be carried out. After the patient is convalescent antiseptic gargles should be continued. For this purpose use:

℞ Crystalline carbolic acid ..... ʒ i.
Alcohol ..... ʒ vi.
Essence of peppermint ..... gr. xv.
S. Eight to ten drops in a glass of water.

Ether in Labor.—The *Northwestern Lancet*, November 1, 1896, recommends ether for the following reasons: 1. The inhalation of ether procures for the patient a more or less perfect immunity from the conscious pain and suffering attendant upon labor. 2. It does not, however, diminish the strength or regularity of the contractions of the uterus. 3. It sometimes increases them in strength and number. 4. The contraction of the uterus after delivery seemed perfect and healthy when it was administered. 5. Its employment not only saves the mother from pain in the last stage of labor, but also in some degree from the occurrence and consequences of the nervous shock attendant upon delivery. 6. Its exhibition does not seem to be injurious to the child.

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

CHOLERA AT PLYMOUTH—DIPHTHERIA IN LONDON—PROFESSOR HUGHES' MUNIFICENCE—OVERCROWDING THE PROFESSION—CLINICAL SOCIETY—GUNSHOT WOUND OF EYE—TACHYCARDIA—FRACTURE OF AXIS—MEDICAL SOCIETY—WANDERING SPLEEN—PNEUMOTHORAX—HOSPITAL ABUSE—LORD LISTER.

London, January 15, 1897.

You have no doubt heard by cable of the arrival of a cholera-infected ship at Plymouth and the steps taken by the sanitary and military authorities, which so far have sufficed and once more show the superiority of our modern preventive measures. It seems a not altogether improbable contingency that a plague-infected vessel may appear at one of our ports, and a constant watch is being kept on the coast as to all such dangers. The subject is a common one of conversation, but no one seems to anticipate any serious invasion. We are more concerned about the mortality from diphtheria, which rose last week to 71, no less than 30 above the corrected average for the same week of the decade 1887–96. The numbers for the three preceding weeks were 58, 38, and 49.

I hear that measles is very prevalent in Dublin just now, and, although scarlatina has somewhat abated, the hospitals are all full.

Professor A. Hughes is obliged to relinquish his work at Cardiff on account of the health of his wife. That the University College may not suffer, he has offered to leave his very valuable anatomical collections, and in the event of his desiring in the future to take them away, he presents a sum of money to replace them. This is certainly a munificence that could never have been anticipated from the short time in which he has held the chair, but it signalizes the tenure of the first occupant as much as his remarkably successful teaching.

The overcrowded state of the profession is notorious, but the inrush continues. The new medical directory contains nine hundred and fifty-eight names more than that of the last yearly issue. The increase is above that of any year except 1894. Parents may well pause before deciding to educate their sons for an impoverished profession, in which the competition is ever increasing. The increase is not local, but obtains throughout the islands.

I wonder if a knowledge of this pressure has any influence in maintaining the obstinate refusal of the "military advisers" to do justice to medical officers. If so, they may yet be brought to reason. I hear that there are a couple of candidates for the next examination. Others may follow before the time, but scarcely in numbers to fill up vacancies, and the "military advisers" are at their wits' end.

On Friday at the Clinical Society Mr. Brudenell Carter gave an account of a gunshot wound of the eye received by a lad of fourteen from a gun, the muzzle of which was only three yards away. Most of the charge entered the mouth, doing much injury; but two of the pellets of snipe shot passed through the left lower lid and entered the eye, piercing the sclera below the cornea, one just to the nasal side of the vertical meridian, the other on the same horizontal line, four or five millimetres nearer the nose. On seeing the subject two days after the accident, Mr. Carter dilated the pupil and found that the retina had been wounded. The eye recovered; the retina and choroid disappeared from a considerable region, it was supposed by retraction, leaving the internal surface of the sclera exposed to view, and on the margin of this gap the two pellets are encapsuled. Vision now equals ten-twelfths of the normal, and the lad is well. In reply to questions, Mr. Carter said injuries by heated missiles acted as though sterilized, and therefore it was safe to wait before removing an eye unless the injury was such as to render recovery impossible. Sympathetic ophthalmia rarely begins before three weeks. He added that removal was an unsurgical proceeding, since Mule's operation permitted the fitting of a glass eye which moved almost as well as the sound one. He had a patient so fitted who would bet with persons that they could not tell which was the glass eye.

At the same society Dr. Herringham related a case of paroxysmal tachycardia in a child. He saw her when she was eleven years old, and the fits were said to have begun seven years earlier. They came on suddenly and lasted from thirty-six hours to thirteen days, usually passing off in sleep, so that the child with a beat of 240 to 260 at night would wake with 90 in the morning. Sudden efforts or movements seemed capable of exciting attacks. No valvular disease could be detected; there is no history of rheumatism or syphilis. The heart is now enlarged, and it was suggested that there might be adherent pericardium or that the myocardium might be unhealthy as the result of some former disease. These cases are rare, as observed by several speakers, especially in children. They are mostly associated with visceral disorder, general abdominal. The suggestion that they depend on irritation of the sympathetic is natural, but no experimental irritation will produce such rapidity. Even when the vagus is divided the rate is not so high, and it is, of course, constant, not paroxysmal. No kind of treatment has been found of any use, and no one was able to give therapeutic suggestions of any importance. Rosenfeld recently reported three cases treated by compression of the thorax and abdomen.

Mr. C. S. Wallace then reported a case of fracture of the axis in a man, aged forty-four years, from a fall of about nine feet. He was put to bed while unconscious. The next day he complained of stiffness, and the head was protruded and the chin nearly touched the sternum. A slight projection of the cervical spine was felt in the pharynx. The rigidity passed away and he seemed nearly well on the eighth day, but died suddenly. Post mortem it was found that fracture of the axis separated the superior articular parts from the odontoid process. No injury of the cord was found.

On Monday Mr. Bland Sutton brought forward at the Medical Society the subject of wandering spleen. This curious condition produces various effects on the organ itself and on neighboring viscera. On the former, engorgement or axial rotation causing atrophy is most common. As to other organs, the pancreas may be dragged out of place or the chief drag may be on the stomach, giving rise to dilatation, or again the intestines may be so dragged upon as to cause jaundice from obstruction to the escape of bile. The lengthened pedicle, too, may cause intestinal obstruction. Further, retroversion and prolapse of the uterus may be caused by pressure of the displaced spleen. Death has resulted in such cases from rupture of the stomach or duodenum, or of the spleen itself, or from splenic abscess or intestinal obstruction. Considering the practical impossibility of suturing the viscus and the good results of its removal, Mr. Sutton advises splenectomy. Mr. Ballance mentioned that he had met with cases in which after operation symptoms occurred such as have followed experimental removal in animals, viz., anorexia, emaciation, profound anæmia, enlargement of all the external glands.

Dr. Samuel West afterward read a paper on the "Prognosis of Pneumothorax." He found death might occur from the effects of the original disease, *e.g.*,

phthisis, or of the lesion itself, or from secondary empyema.

The Royal College of Physicians in Ireland has passed a resolution condemning the employment of unqualified assistants by any of its licentiates. Other boards please copy.

Hospital abuse was well illustrated in the high court on Tuesday. As reported in Wednesday's newspapers, the unfortunate owner of three public houses met with an accident, was treated at a hospital, and subsequently received attention as an out-patient for "some time." The poor fellow's takings fell off during his illness. Ultimately the impoverished publican had to sell his houses at the miserable price of £21,000. I wonder if either of his hospital doctors could realize so much from depreciated property.

Lister is not to be merged in another name. I am glad to hear that in accordance with precedents I quoted he will take for his title Lord Lister, so that the name he has made famous will still be familiar.

CATARRHAL SALPINGITIS.

To the Editor of the Medical Record.

Sir: Allowing that Dr. Vineberg in his article entitled "Acute Catarrhal Salpingitis—Its Resemblance to Appendicitis—Differential Diagnosis—Treatment" did not report Case III. as catarrhal salpingitis, I would still ask: "Did the woman live because of the operation or in spite of it? If she had received the same treatment before the operation that she did when her life was despaired of, would she not have escaped both the operation and the premature birth of her child? What benefit did she receive from the operation? Is it not a better illustration of the mania for operating than of 'general peritonitis in some obscure way depending upon the generative organs?'" I did say: "I saw nothing alarming in her condition as reported." I did not refer to her condition after the operation and the forced delivery of her child, but to her condition at the time of the operation. If Dr. Vineberg will look at his article he will see, I think, that the temperature did not rise to 104.8° F. and the pulse to 170 to 180 until after the operation and the birth of the child. There was little vomiting previous to the operation. After the operation I looked upon her condition as extremely serious, and my anxiety would have been more than "considerable."

Adelaide Lambert.

263 Orange Street, New Haven, Conn.

EMESIS AND INTUBATION.

To the Editor of the Medical Record.

Sir: A letter from Dr. J. O'Dwyer in the Medical Record concerning a certain modification of the intubation tube contains a statement which I think will bear criticism. I infer that Dr. O'Dwyer believes that emesis is possible while the tube is in the larynx.

Having observed that vomiting never occurred in any of my own cases, it called to mind the fact that closure of the glottis is a very important part of the physiological act of vomiting. Vigorous expiratory effort with closed glottis is the essential expelling force, and not contraction of the stomach itself.

I have also observed that as the dyspnœa of croup becomes extreme, emetics fail to act, because the approaching asphyxia prevents even momentary cessation of respiration. The little sufferer has barely time even to swallow. The fact that the disturbed respiration can prevent even heroic doses of emetics from acting emphasizes the importance of closure of the glottis as a factor in emesis.

Following the establishment of easy respiration by intubation, we can often observe all of the physiological actions of emetics except emesis. Prostration, a rapid pulse and salivary flow, and paleness about the mouth, followed by more or less colic and sometimes diarrhœa, are often caused by the accumulated emetics becoming gastro-intestinal irritants.

Dr. Charles L. Greene, of St. Paul, made a suggestion based upon these physiological facts for the treatment of certain forms of uncontrollable vomiting. He proposes to intubate, and, as I understand him, he bases his advice upon the physiological teaching that closure of the glottis is necessary to emesis rather than upon experience in intubation.

Dr. O'Dwyer's experience and practical studies on this question will surely enable him to affirm or deny the teachings of physiology on this point.

With reference to the modified tube, only time and experience can determine its merits. Whether or not the tube perfected by Dr. O'Dwyer be changed cannot detract from the honors which he has earned. He will ever be revered by our profession. His name, with Myers, of Copenhagen, will be prominent in this period of medical history as that of one of the great benefactors of the children of the poor.

Thomas Hubbard, M.D.

Toledo, Ohio, January 16, 1897.

"APPENDICITIS" VERSUS "SCOLECITIS."

To the Editor of the Medical Record.

Sir: The heading of Dr. Gerster's able letter in the last issue of the Medical Record, namely, "Let Us Abolish 'Appendicitis,'" must have carried joy and consternation to the hearts of the numerous but varied readers of your valuable weekly—joy to that timid band who, with the populace, share the perpetuate fear of getting into inflammatory relations with the organ of primitive utility but modern cussedness; and consternation to that formidable army whose gory hands are forever ready to attack it at the slightest provocation. However, the doctor's subsequent remarks dissipated the charming idea of his philanthropic motives, but rather stamps him as a genuine though belated "reformer."

Regarding the proposed change of the nomenclature expressing the pathological condition of the appendix vermiformis and its surgical therapeutics, the unsophisticated reader might be pardoned for repeating the poet's question: "What's in a name?" It is evident from daily experience that the appendix will be a nuisance under any name! And inasmuch as medical men all the world over fully appreciate the various abnormal processes that that relic of former anatomy is heir to, denominated and designated by the now familiar term "appendicitis," it would seem needless and useless at this late hour to find fault with it or to substitute for it some new and unfamiliar name, which may take years to popularize. A more profitable crusade would be this: Abolish that form of medical nomenclature which contains no suggestion of the pathology, clinical picture, or location of the disease thus characterized. It is rather named after the man "who first described it." The number of such diseases is legion. If Dr. Gerster would let his ponderous sledgehammer fall on this kind of unscientific nomenclature, this silly dilettantism, he will not only strengthen the respect but will gain the everlasting gratitude of an outraged profession.

The only excuse I can find for "abolishing" the "cacophonic 'appendicitis'" and adopting instead the "euphonic 'scolecitis,'" is a humane consideration for the frightened public. The word "appendicitis" bends the knees of the healthy, and strikes terror into the

hearts of the afflicted members of the community. "Scolecitis," therefore, being fresh from the mint and hence unknown to the general public, will be comparatively tame, mild, horrorless. Furthermore, a patient will more readily submit to "scolecotomy" and "scolecectomy" than to "appendectomy" and "appendicectomy," for the same reason, for example, that some of our wise laity exhibit a decided repugnance to mercury but cheerfully take hydrargyrum.

SCALPEL.

NEW YORK, January 25, 1897.

ON PALPATION IN INTERVAL APPENDICITIS CASES.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: Is my experience any different from that of other surgeons in the matter of accurate palpation of infected appendices? Probably not. A physician sends a case of suspected appendicitis to the office for examination. A diagnosis of empyema of the appendix or of incarcerated concretion is easily made out, and operation is advised. The patient is uneasy and goes to high authorities among general diagnosticians. After a while he returns and says that he wants an operation. He says that he paid the general diagnosticians from ten to twenty dollars apiece. They did not employ any method of examination which inspired his confidence. He knows that they did not feel of his appendix, and he says that he does not care to rely upon their opinions. Probably every surgeon who is much engaged in abdominal work will testify that this is a common experience, and the interesting part of the matter is the speculation as to how many such subjects are going about with easily discoverable lesions. One of my patients saw so many diagnosticians in so many cities that as a matter of curiosity I asked him to write out a list of opinions received, numbering the physicians but not giving their names, and dating from the time when the pain in the iliac region first started him off on his rounds in seeking relief.

Letter of J. W. J——, Springfield, Ohio, December 20, 1896.—"Dr. A, March, 1891. Diagnosis, catarrh of stomach and bowels. Advice, internal treatment by drugs.

"Dr. B, July, 1891. Diagnosis, malarial fever. Advice, internal treatment by drugs.

"Dr. C, May, 1892. Diagnosis, inaction of liver. Advice, internal treatment by drugs.

"Dr. D and son, June, 1892. Diagnosis, dyspepsia. Advice, internal treatment by drugs.

"Dr. E, January, 1893. Diagnosis, constipation and indigestion. Advice, treatment by drugs.

"Dr. F, May, 1893. Diagnosis, catarrh of bowels. Advice, treatment by drugs.

"Dr. G, June, 1893. Diagnosis, lung trouble; catarrh of stomach and rectal trouble; also lump in right side, which he could not diagnose. Advice, internal treatment by drugs; operation for rectal ulcers; 'let lump alone if it will let us alone.'

"Dr. H, August, 1893. Diagnosis, intestinal indigestion; afterward appendicitis. Advice, internal and external treatment by drugs and poultices till cold weather; then operation.

"Dr. I, August, 1893. Diagnosis, appendicitis. Advice, treatment by drugs till acute attack; then operation if necessary.

"Dr. J, August, 1893. Diagnosis, appendicitis. Advice, internal treatment by drugs, external by salt-water pack at night, and injections of olive oil; operation later if treatment failed.

"Dr. K, August, 1893. Diagnosis uncertain; no signs of appendicitis, but indications of small tumor pressing on bowel somewhere. Advice, internal treatment by drugs.

"Dr. L, September, 1893. Diagnosis, appendicitis. Advice, no operation.

"Dr. M, January, 1894. Diagnosis, catarrh of stomach and rectal ulcers. Advice, treatment by drugs; siphon for stomach.

"Dr. N, January, 1894. Diagnosis, dead and loose kidney. Advice, operation.

"Dr. O, January, 1894. Diagnosis, tumor. Advice, exploratory operation.

"Dr. P and son, February, 1894. Diagnosis, catarrhal condition of bowel, with inflammation and adhesions. Advice, internal treatment by drugs. Afterward they diagnosed appendicitis, and advised operation."

This patient had a colloid carcinoma of the appendix, which had advanced at the time of my operation to include a part of the cæcum. He has continued to engage in business, although I have had to resect intestine for him four times, whenever recurrent carcinoma appeared in other parts of the bowel. This could probably have been all avoided if an accurate palpation and a modern procedure had been the result of his first application for help.

Unless a physician has adopted one of the satisfactory methods for palpation of the appendix and is able to determine accurately the length, breadth, position, and condition of the average appendix that requires examination, he should be very cautious about expressing any opinion in the case, because that opinion is likely to be depended upon by a patient who puts confidence in his physician.

According to the estimates which I published in the MEDICAL RECORD for December 26, 1896, more than two hundred thousand new cases of appendicitis come into the hands of physicians of the United States annually; and if surgeons are to judge from what patients tell them about examinations that have been made, not many of these appendices are accurately palpated.

ROBERT T. MORRIS, M.D.

49 WEST THIRTY-NINTH STREET, NEW YORK,
January 22, 1897.

A FEW FACTS RELATING TO THE NON-CONTAGIOUSNESS OF PULMONARY CONSUMPTION.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: Your timely article on "The Health Board and Compulsory Reports" will, I am sure, be heartily approved, if not by the entire medical profession, at least by all who have had opportunities of observing cases of pulmonary consumption. To the large number of physicians engaged in active practice (not including, of course, those whose experience is limited to the four walls of the bacteriological laboratory), the action of the board of health in classing consumption with contagious diseases would appear ridiculous, were it not for the suffering and annoyance it will entail upon the many afflicted with that disease.

Without entering upon a discussion concerning the contagiousness of consumption, which I do not admit except to an extremely limited extent, I beg to call attention to a few facts bearing upon the question which I have collated. Knowing that there are more cases of pulmonary consumption at Colorado Springs, in proportion to its population, than in any other city or town in the United States and perhaps in the world, I wrote some time ago for information to Dr. S. E. Solly, of that city, well known as a writer on consumption and climatology, and whose experience in the treatment of that disease has been large and extends over a period of many years. In reply I received the following:

"The dangers of contagion from a consumptive are so easily controlled that it is by no means necessary

to separate consumptives from healthy persons. You ask me concerning my experience here. At least a third of our population are consumptives. The town, which contains some fifteen thousand people, has been established twenty years. An inquiry made by disinterested physicans into the number of cases of consumption that were known to have originated in the town resulted in a report of twenty in all. Although it is probable that our brilliant sunshine and dry air more quickly destroys the vitality of the bacilli than your Eastern atmosphere, yet in the poorer lodging-houses of the town there are many ill-ventilated rooms, inside or on the north side of the building, inhabited by consumptives and their families, where recklessness of expectoration and carelessness of ordinary cleanliness are marked features of their domestic *ménage*; yet cases of contagion do not average more than one a year."

At Colorado Springs the consumptives mingle with the other residents of the city on all occasions—at church service, theatre, concerts, and in the overheated and crowded rooms of private residences during social functions; they reside in the same hotels, boarding-houses, and private dwellings with those not afflicted with the disease, and no attempt at isolation has been made. Notwithstanding this apparent indifference on the part of the local authorities to the contagiousness of the disease, only twenty cases have originated in Colorado Springs in twenty years.

At Davos Platz in Switzerland, where I spent a winter a few years ago, a very large number of consumptives were staying. The hotels were crowded, and of the fifteen hundred strangers in the village, about one thousand were consumptives. At the hotel at which I stayed there were about one hundred and twenty guests, about eighty of whom were consumptives. At Davos, during the winter, the invalid's day for outing is limited to four and one-half hours; the remainder of the twenty-four hours is spent within doors. No one stood in dread of contracting the disease, and no cases occurred in which it was conveyed from person to person. No special precautions were taken by the physicians and local authorities to prevent contagion, other than good ventilation of the living and bed rooms. As in Colorado Springs, no cases of the disease originated at Davos.

It is almost impossible to estimate the suffering and annoyance that will follow the enforcement of the unjust and unwise order of our board of health. Smaller cities throughout the country are preparing to follow the example set them by New York. At health resorts, snobbish landlords, desiring to adopt the latest fad and to cater to notoriety, insert in their circulars soliciting patronage that cases of pulmonary consumption are not received. Let the order be enforced strictly, and consumptives will in time be avoided and shunned as is the leper or the victim of small-pox.

Consumption always has prevailed and always will prevail in New York, notwithstanding the efforts of a board of health, composed of four laymen and only two physicians, to prevent it.

If they honestly wish to lessen the number of cases, let them endeavor to cut off one of the most prolific sources of the disease—milk and beef. In tuberculin we have an infallible test for detecting tuberculosis in cattle. Let the board of health make frequent examinations and applications of that test, and have killed the cows that respond to it. It will cost the State a great deal of money, but it will be cheaper in the end than building and maintaining hospitals in a city that has even now more than it really needs. Enforcing its order against the filthy and disgusting habit of spitting in cars and public places will lessen the danger of contagion.

CLINTON WAGNER, M.D.

19 EAST THIRTY-EIGHTH STREET.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending January 30, 1897:

	Cases.	Deaths.
Tuberculosis	179	139
Typhoid fever	6	1
Scarlet fever	170	7
Cerebro-spinal meningitis	3	1
Measles	185	4
Diphtheria	268	34
Laryngeal diphtheria (croup)	12	5
Chicken-pox	27	0

Stomach Digestion.—As early as ten or fifteen minutes after taking food, the stomach contents obtained are acid, the acidity depending for the first half-hour upon the presence of lactic acid. For the next half-hour hydrochloric acid exists with the lactic acid; but after the first hour hydrochloric acid alone should be found. Lactic, acetic, and butyric acids are not secreted by the gastric glands, but are either swallowed with the food, or formed in the stomach from the non-nitrogenous part of the food by bacterial ferments.—MURDOCH.

The Medical Liar.—Plagiarism is a personal sin, and he who thus sins does but little harm to his fellows. But quite different is the medical liar. He sins not only against himself, but against his fellows. It makes little difference whether he lies with the direct and deliberate intention of deceiving, or from criminal negligence in ascertaining the truth. In either case he is a public nuisance and an enemy to the profession.—*Archives of Pediatrics.*

Phobias.—In a recent work of M. Gélineau on "Unhealthy Fear, or Phobiæ," the author gives a complete list of these morbid mental conditions. They are aichmophobia, or fear of sharp points, as of needles or pins; agoraphobia, or fear of open spaces, with a subvariety; thalassophobia, or dread of the ocean; astrophobia, or fear of the stars and celestial space; claustrophobia, or fear of enclosed spaces; mysophobia, or fear of filth; hæmatophobia, dread of blood; necrophobia, or horror of dead bodies; thanatophobia, or dread of death; anthropophobia, or fear of crowds; monophobia, a fear of being left in the solitude; bacillophobia, or fear of microbes; siderodromophobia, or dread of railways; pathophobia, or fear of disease, with many subdivisions, of which the most important and most frequent are anginophobia (fear of angina pectoris), ataxophobia, syphilophobia, lyssophobia (or fear of rabies), spermatophobia, and zoöphobia (or fear of animals), which in its turn has subdivisions for cats, dogs, horses, mice, etc., *ad totum catalogum animalium.* Further, we find in the same list kleptophobia, fear of becoming a kleptomaniac; pyrophobia, fear of matches; stasophobia, dread of standing upright; aerophobia, or dread of draughts of air; acrophobia, fear of high places; toxicophobia, a fear of poisons; demonophobia, a dread of the devil (this is rather rare). There are also a great number of phobiæ peculiar to certain professional persons, as physicians, artists, merchants, which have yet to be Hellenized and classified. The culminating fear, however, the quintessence of dread, is the fear of having a fear, the dread of a dread, or phobophobia. The study of these phobiæ opens up a large subject, and the long names will be hailed with delight by some unscrupulous members of our profession. In calming (or humbugging?) hysterical patients some of them would be invaluable, for that useful and elastic term

"neurasthenia" is getting a bit played out among the laity. The hypochondriac old lady who tells her sympathetic medical attendant that even to think of "travelling by a horrid railway train sets her all of a tremble" will be greatly calmed and edified when Dr. Wosky gravely replies that such a statement does not surprise him, as she is suffering from that curious and interesting complaint called siderodromophobia!—*Medical Times and Hospital Gazette.*

What is in the Appendix?—An exchange in the *Northwestern Lancet*, December 15, 1896, makes the following interesting statement: "Autopsies upon 400 persons dying of various diseases showed fæcal concretions in the appendix in ten per cent., while in Renvier's collection of 454 autopsies after appendicitis there were found 179 concretions and 16 foreign bodies in this organ. Hawkins examined 60 fatal cases of appendicitis and found no foreign body whatever. Fitz analyzed 300 cases and found concretions in five per cent.

The Differential Diagnosis of Vascular and Muscular Tinnitus Aurium.—One variety is caused by the flow of blood through the irregular-calibred blood-vessels of the internal ear and those in the neighborhood, producing vibrations by the passage of the blood. This I have named vascular tinnitus aurium. The other variety is produced by the action of diseased muscles of the middle ear, producing vibrations by alternate contractions and relaxations. This I have named muscular tinnitus aurium. Many persons who are partially deaf and experience excessive noise in their ears, will hear a conversation in a moving railroad coach better than in a quiet room. This is positive proof that all such persons are afflicted with muscular tinnitus aurium. The sound or sounds that are formed in the internal ear and its neighborhood, *i.e.*, vascular tinnitus aurium, will not be decreased in any degree by extrinsic noises of any kind. It is often of the utmost importance to be able to differentiate between the two kinds of tinnitus, for a treatment or procedure that would be of great value to a patient suffering from the muscular variety would be decidedly injurious, if not disastrous, to one suffering from the vascular variety, and *vice versa*.—Dr. Rumbold, *St. Louis Medical and Surgical Journal.*

Saltness of Sea Air.—Dr. Chaix, wishing to find out whether in calm weather the air of the seashore contains an appreciable quantity of sea salt, has made a series of experiments. In each experiment he caused by means of an aspirator a thousand litres of air to pass through a solution of nitrate of silver. In every case there was not the least cloudiness of the solution, proving that the air contained no salt. This is not at all surprising. It is well known that the air contains salt only when the wind carries off mechanically salt spray from the wave crests; the salt of sea water cannot evaporate into the atmosphere. The evident conclusion is that to obtain the beneficial action of sea air we must go where the air is sufficiently agitated by the wind continually to hold sea water in suspension. It is not enough, then, for the invalid to go to Brittany or some such calm shore; we should prefer rather somewhat more windy coasts, as those of Picardy and Normandy, where the air is almost always charged with saline particles raised from the sea by the wind. Such localities are infinitely more beneficial and active.—*Revue Scientifique*, January 11th.

The Abuse of Nervous Stimulants.—The *Therapeutic Gazette*, November 16, 1896, in an editorial, calls attention to the fact that both the medical profession and the laity have been accustomed to the abuse of alcohol as a nervous stimulant. This excessive use has hardened some to its evil effects, while others go to the opposite extreme in condemning it. There is an ever-increasing number of substitutes for alcohol thrown upon the market, such as coca, kola, etc. Many of these substitutes contain a large quantity of alcohol, and the consumers of them become addicted to the alcoholic habit without being aware of the fact. The temporary changes for the better which the consumer notes after a dose of his favorite remedy are usually due to the alcohol that it contains. We are accustomed to consider the widespread use of nerve stimulants to the rush and pressure of modern life, but history shows that for many hundreds of years nerve stimulants have been used and abused much as they are to-day. The abuse of these remedies by the profession is rather the result of carelessness than of ignorance. They should be used only as temporary makeshifts, as in the vast majority of cases they materially increase the discomfort and ill health of the patient. All the so-called "strengthening remedies," which enable a man to accomplish more work when he is under their influence, do this, not by adding units of force to his body, but by utilizing those units which he has already obtained and stored away as reserve force. The result will be the same as in the case of a banker who draws upon his capital or reserve funds to supplement the money with which he could properly carry on his business. The result is in the latter case a pecuniary, and in the former a nervous bankrupt.

Death Eighteen Hours after the Introduction of a Bougie into the Urethra.—Dr. Muller, according to a statement published in the *Medical News*, has reported the case of a man, aged thirty-eight years, with a history of gonorrhœa in youth, who came under observation on account of some difficulty in micturition. He had previously been treated for stricture of the urethra. The urine was turbid, and passed in a small stream. A diagnosis of vesical catarrh, with moderate stricture of the urethra, was made, and to determine the degree of narrowing metallic sounds were employed. A No. 21 conical instrument, with a long curve, was first gently introduced, with due antiseptic precautions, and an impassable obstruction encountered in the membranous urethra. With still greater care, a No. 23 sound was next used, but also without success. The examination was unattended with pain, and but little blood was lost. A prescription containing uva ursi and sodium bicarbonate was given, and the patient sent home. Three or four hours after the manipulations, and immediately upon taking his medicine, the patient was seized with vomiting and diarrhœa, followed by chills, restlessness, general prostration, pains in the chest and in the sacral region, and excessive thirst. Eighteen hours after the use of the bougies the patient died, amid symptoms of cardiac failure. Upon post-mortem examination the heart was found to be slightly fatty and the lungs were œdematous. There existed cloudy swelling of liver, spleen, and kidneys. Portions of kidney were put aside for histological examination, to determine if nephritis existed, but were inadvertently lost. The ureters and pelves of the kidneys presented no abnormality. A tight circular stricture was found involving the membranous urethra, and, close by, several diverticular depressions of the urethral mucous membrane were found, one of which appeared to have been recently eroded. Copious greenish pus escaped from the prostate gland. The mucous membrane of the bladder was in a catarrhal state; the viscus contained a small amount of turbid urine. The opinion is expressed that the fatal issue in the case reported is to be attributed to an acute nephritis, induced, perhaps, through the introduction of pus from the prostate through the erosion in the urethra.

A FURTHER STUDY OF TUBERCULOUS INFECTION OF DUST.[1]

BY IRWIN H. HANCE, M.D.,

NEW YORK.

DURING the previous winter and spring the writer undertook to study the infectiousness of dust with tubercle bacilli in various localities in this city—tenements, hospitals, reception room of ore dispensary, and the public conveyances. It is his pleasure to present to the academy to-night the results of his investigations. The work was done at the request of Dr. Herman M. Biggs, pathologist to the health department, who kindly placed at the writer's disposal the privileges and advantages of the laboratory of the health board; and to him and Dr. William H. Park the writer wishes to express his full appreciation of the kindness and assistance extended to him in the pursuit of his work.

As regards the tenements, it was sought to prove how efficacious were the rules and regulations prescribed in the board-of-health circulars in preventing infection. Four specimens of dust were taken from tenements where the people were intelligent and in appearance cleanly about their persons and quarters. As a contrast, three dirty tenements were examined, in which the medical inspectors reported that the measures for preventing infection and contamination of the quarters were not being properly carried out.

The two hospitals were Bellevue and Charity, under the care of the city; and the waiting-room of the out-door poor of Bellevue Dispensary. The public conveyances were the elevated cars, and two of the old Broadway horsecars, now in use on the Avenue C and Houston Street line.

The method[2] of procedure was the same as was used in the examination of the cottages in the Adirondack Cottage Sanitarium, and the inoculated animals were all young guinea-pigs. The experiments in detail were as follows:

EXPERIMENT I.—Tenement, 338 East Thirty-second Street; basement room, occupied six months. Phthisical woman in bed three weeks before her death. Expectorated into cloths and paper, which were burned at once. Four animals inoculated. No. 1, sixteen square inches of dust from top of door; died on fourth day. No. 2, twelve square inches from cot bed; died in thirty-six hours. No. 3, twenty square inches from surbase; died in thirty-six hours. No. 4, thirty square inches from wall paper; killed on fifty-fourth day; negative.

EXPERIMENT II.—Tenement, 330 East Forty-seventh Street; two back rooms. Case of laryngeal phthisis; two months in rooms, two weeks in bed. Expectorated into bowl with water in it, emptied frequently into sink in hallway. No. 1, twenty square inches from top of door; died in thirty-eight hours. No. 2, sixteen square inches from end pieces and sides of bed; killed on fifty-seventh day; negative. No. 3, twenty square inches from surbase; killed on fifty-seventh day; negative. No. 4, thirty square inches from wall paper; killed on sixty-second day; negative.

EXPERIMENT III.—Tenement, 237 East Fifth-fourth Street; two back rooms. Phthisical woman, four years in rooms, six months sick, three weeks in bed. Expectorated into water in spittoon, emptied four times a day. Inside dark room examined; had been repainted. No. 1, twenty square inches from top of door; killed on fifty-seventh day; negative. No. 2, sixteen square inches from bed slats and springs; killed on fifty-first day; negative. No. 3, twenty square inches from surbase; killed on fifty-first day; negative. No. 4, thirty square inches from wall; died on third day.

EXPERIMENT IV.—Tenement, 105 East Thirty-fourth Street; rooms above unoccupied stable. Three months in rooms, ten days in bed. Used sanitary cuspidors, which were burned. No. 1, ten square inches from top of door; killed on fifty-seventh day; negative. No. 2, ten square inches from surbase; killed on fifty-seventh day; negative. No. 3, twelve square inches from bed and springs; killed on fifty-seventh day; negative. No. 4, twelve square inches from bed and springs; killed on fifty-seventh day; negative.

EXPERIMENT V.—The following isolated experiment is here introduced as added proof that rooms need not be infected by tuberculous patients. Infirmary of the Adirondack Cottage Sanitarium. The patient was bedridden and helpless for three months; expectorated into Japanese napkins, which with pasteboard receptacle were burned several times a day. No. 1, forty-nine square inches from stand by bed; killed on ninetieth day; negative. No. 2, forty-nine square inches from wall by head of bed; killed on ninetieth day; negative. No. 3, thirty square inches from bed and springs; killed on ninetieth day; negative.

EXPERIMENT VI.—Fourth-floor tenement flat, 221 East One Hundred and First Street; five rooms, in which two sons had died, one two months, the other two weeks ago. Expectorated into water in a cup, changed three times daily. Each patient was bedridden one month. Dirty appearance in apartment. Nos. 1 and 2, nine square inches from top of shelf and casing of door in inner room. Nos. 3 and 4, six square inches from surbase of inner room. No. 1, killed in sixty-five days; negative. No. 2, killed in sixty-five days; glands and spleen enlarged; two spots in lung indicative of tuberculosis, but no tubercle bacilli were found. No. 3, killed in sixty-five days; advanced tuberculosis. No. 4, killed in twenty-eight days; tuberculosis of glands, spleen, and lungs; tubercle bacilli found.

EXPERIMENT VII.—Tenement, 331 East Forty-seventh Street; two rooms. Alcoholic woman, been in room five months. Filthy quarters. Nos. 1 and 2, eighteen square inches from surbase and end of cot. Nos. 3 and 4, ten square inches from top of wainscoting. No. 3 died in forty-eight hours. Nos. 1, 2, and 4 killed on sixty-ninth day; negative.

[1] Read before the New York Academy of Medicine, January 21, 1897.

[2] MEDICAL RECORD, December 28, 1895, vol. xlviii.

Experiment VIII.—Tenement, 325 East Forty-third Street; three rooms on ground floor. Nursing mother, with two other children under four years about; been ill four months. Very dirty quarters. Spit into rags. Nos. 1 and 2, four square inches from bed and springs. Nos. 3 and 4, six square inches from surbase. No. 3 died in twenty-eight hours. Nos. 1, 2, and 4 killed on fifty-third day: all extensively tuberculous; tubercle bacilli found.

Experiment IX.—Bellevue Hospital. Ward 25: Three square inches from surbase by bed of phthisical patient; killed in sixty-five days; negative. Three square inches from stand of bedridden patient: killed in sixty-nine days: negative. Ward 20: Four square inches from stand; killed on sixty-fifth day: negative. Three square inches from surbase; died in six days. Ward 16: Four square inches from surbase: killed on sixty-seventh day; negative. Four square inches from card rack and stand: killed on sixty-ninth day; negative. Marquand Pavilion: Four square inches from stand; killed on sixty-ninth day; negative. Three square inches from surbase: killed on sixty-ninth day; negative. Sturgis Pavilion: Three square inches from surbase: three square inches from behind radiator; killed on sixty-ninth day; negative. Ward 18: Four square inches from surbase; four square inches from rods and slats of bed: killed on sixty-ninth day: negative.

Experiment X.—Charity Hospital. Ward 8: Three square inches from surbase. Female Ward 2: Three square inches from bed slats. Female Ward 2: Three square inches from surbase. Male Ward 2: Three square inches from bed slats. Male Ward 2: Three square inches from surbase. All of these were killed on the sixty-first day; all negative. Ward 9: Three square inches from behind wardrobe; died in two days. Gerry Pavilion: Three square inches from behind radiator inoculated into two pigs; killed on sixty-first day; both negative.

Experiment XI.—Bellevue Out-Door Poor. Nos. 1 and 2, three square inches from surbase in middle of waiting-room. Nos. 3 and 4, three square inches from surbase near where the spittoons were piled up. No. 1 died in three days. No. 3 died in five days. No. 2 killed in sixty-five days; extensively tuberculous: tubercle bacilli found. No. 4 killed in sixty-seven days: negative.

Experiment XII.—Elevated railroad cars. Twenty square inches of dust taken from under the seats in two cars, Nos. 1,042 and 1,080. Four guinea-pigs inoculated with dust from each car. Seven died in twenty-four hours. One killed on fifty-fifth day; negative. Ten square inches of dust from car No. 1,079, inoculated in four pigs. One died in three days. Three killed in sixty-seven days: negative. Ten square inches from car No. 1,079, inoculated into four pigs. One died in two days. Three killed in sixty-four days; negative. Ten square inches of dust, which had been kept sealed in a drawer for over two months, from car No. 1,079, inoculated into one pig; killed on sixtieth day; negative.

Experiment XIII.—Avenue C and Houston Street line. Car 8: Fourteen square inches inoculated into four pigs. One died in four days. Three killed in sixty-eight days; two negative: one actively tuberculous—tubercle bacilli found. Car 20: Twelve square inches inoculated into four pigs. One died in two days. Three killed in sixty-eight days, negative. Car 20: Twelve square inches of dust, which had been kept sealed in a drawer for over two months, inoculated into one pig; killed in sixty days: negative.

To summarize: Of sixteen pigs inoculated with dust taken from four tenements where the family had paid attention to the instructions and regulations given them, five died of acute infection, and none was affected with tuberculosis. Of twelve pigs inoculated with dust from suspected rooms, two died of acute infection, one was indicative of tuberculosis, and five were tuberculous: and two tenements out of three were found infected. In Bellevue and Charity hospitals eleven wards were examined, with negative results. Of four animals inoculated with dust from the waiting-room of the out-door poor, two died of acute infection and one was tuberculous. Of the elevated railroad cars, none was found infected with tubercle bacilli, but the dust was highly infectious with other germs, which rapidly proved fatal. Of the street-cars, one of the two examined was infected with tubercle bacilli. Two experiments with dust kept sealed in a dark drawer for over two months, in which ten and twelve square inches were respectively inoculated into two animals, showed that the acute infectious material had died out.

Conclusions.—The small amount of dust which it was possible to inoculate into each animal renders the chance of positive results much smaller than when a considerable area of surface is cleaned and experimented with. The average was but little over three square inches, except in some of the cleaner tenements, while the experiments in the Adirondack Cottage Sanitarium averaged one-half square yard into three pigs. It, however, emphasizes more forcibly the positive results secured. The large number of animals which died of acute infection, had they lived, might have increased the number of positive results. The contrast in the results of the two classes of tenements is most striking and instructive in many ways. It shows that the seed sown by the board of health, in its efforts to enforce compulsory notification of tuberculous cases and subsequent disinfection and renovation of quarters occupied by such people, is bearing good fruit, since all four of the cleanly apartments were free from infection; that the dirtier tenements, by reason of the virulent infectiousness of such small quantities of dust, are sources of great danger to the public. Further, this experiment proves the wisdom of and necessity for granting to the board of health power and authority to order such cleansing and renovation of tenements as they know require it. Knowing how difficult it is to destroy the tubercle bacillus by fumigation or disinfection, it is the writer's opinion that renovation offers more certain means of purifying such quarters than do any processes of disinfection. Finally, the conclusions practically reached by the inspectors as to the existence of infection, as determined by the character of the people and the habits of the patients, are shown to be fairly reliable.

As regards the results obtained at Bellevue and Charity hospitals, it should be a source of gratification to us all that not one case of tuberculosis developed in any of the animals. For we all know what classes of men and women we have to treat in these institutions, and how difficult it often is to enforce sanitary measures among them, owing to their ignorance and absolute indifference to the simplest hygienic principles.

For the same reasons, it ought not to be a matter of any great surprise that the dust in the Out-Door Poor Department was found infected with tubercle bacilli: and one would perhaps be justified in suspecting that the same conditions exist in the waiting-rooms of other dispensaries. The proof of its existence in this one case demands greater care on the part of the managers of such institutions, where so many children are brought to the dispensaries to be treated for other diseases, and while waiting their turn subjected to a real danger of infection with tuberculosis.

Concerning the street and elevated-railroad cars, every physician who considers the existing conditions of local travel in this city would naturally suspect that

the dust in nearly all of them is infected with tubercle bacilli. All that was needed was the proof of its existence in one car for the board of health to call the companies' attention to the fact that the present methods of cleaning the cars were not efficient. One in five cars examined was found dangerous to the health of the travelling public. Consider for a moment how great this danger is, when you know what a small proportion this is of all the cars in use, what a small part of the total area of thickly dust-laden surface was examined; and we may also suspect that the cars which showed negative results may have been similarly infected.

It is not in the writer's province to say how these cars should be cleaned, but there are certain points which are worth considering this evening. The construction of the cars should be such as to have as few recesses and dark corners under the seats as possible. The seats should all be boxed in as on all cable cars now in use. Only metal or wooden slats should be used on the floors; cocoa mats are specially likely to be infected, and become disgustingly dirty. Plush or cloth coverings for the seats should be prohibited; either leather-covered or perforated wooden seats should be used, since they can be easily cleansed. In a few words, the cars should be so constructed that, after having been cleaned with soap and water and some disinfectant, they could all be thoroughly washed out with a hose, the stream being sufficiently powerful to dislodge all dirt that accumulates in the corners.

The above report is presented to you this evening in order to show that the time has come for taking still further measures to prevent infection with tuberculosis. Our milk supply in this city is being carefully supervised by the health board, and at no distant date we may feel confident that this source of danger has been practically eliminated. It now behooves us to safeguard the public against the greatest source of such infection, viz., the dissemination of dried tuberculous sputum in public places and the homes of the poor. To accomplish this in the former places, a vigorous warfare must be waged by the decent members of the travelling public against the filthier class who expectorate anywhere and everywhere. At the same time, the health board must be supported by the various companies and private corporations in its efforts to prevent spitting in public conveyances. The public itself can aid materially in this crusade against the "spitters," by showing plainly its unwillingness to condone the offence any longer.

To lessen this evil in the tenement houses, the ideal way would undoubtedly be to have the State establish a sanatorium for the treatment of the incipient and such advanced cases as could be permanently benefited by climatic treatment, and a hospital in the country close by the city, where the more advanced cases could receive the care that cannot be given to them in their own homes, and which the hospitals, with one or two exceptions, refuse to give to such chronic invalids, owing to scarcity of room and the undesirability of having them in the wards with other patients.

Such institutions should be under the control of the board of health. Its efforts have already met with such success in reducing the mortality from this dread disease that we should all feel encouraged to believe that it will meet with similar success in battling against this infection as it exists in our tenements, public conveyances, and buildings.

Lakewood, N. J.

Ulcus Rodens of the face is treated by the Volkmann curette, followed with an application of chloride of zinc in strong solution.—Paul Dietz.

OBSERVATIONS ON ABDOMINAL SURGERY, WITH RESULTS OF THREE YEARS' HOSPITAL WORK.[1]

By W. GILL WYLIE, M.D.,
new york.

October, 1882, fifteen years ago, when I entered Bellevue Hospital as one of the visiting gynecologists, with the avowed purpose of making abdominal surgery a special work, up to that date there had been only one successful ovariotomy done in Bellevue Hospital. Those interested in and doing general surgery took little interest in abdominal surgery, and ignored gynecological surgery. Very little practical success had been made in abdominal surgery, even by gynecologists in our special hospitals, unless a death rate of thirty per cent. and over could be so considered, and with very rare exceptions the abdominal surgery was confined to simple ovariotomy. February 2, 1887, I reported to this society 125 cases of abdominal surgery, with 12 deaths; and in February, 1888, reported 79 more, making 204 abdominal sections, being all of my operations done from the time I entered Bellevue Hospital, in October, 1882. About half of these were done in the hospital, the others in private practice. Of the 204 subjects, 21 died and 183 recovered—or a little over ten per cent. had been lost.

Before 1888 and for several years later, those who did abdominal surgery were accustomed to receive a great deal of gratuitous abuse and extremely melancholy advice on the subject from those of the profession who were pleased to call themselves conservative. Many of the older and influential men of the profession refused to believe that we were doing anything but spaying women. I recall very clearly the strong opposition to an abdominal section in my first case of appendicitis, twelve years ago (Bellevue), by some of the most eminent physicians and surgeons then on duty. Late in the day, after many trials, I found one consultant who agreed to stand by me. The pus and appendix were found, and the man got well. Later, when I operated for general peritonitis due to intestinal perforation, some of my colleagues among the general surgeons refused to believe that such a case could be saved by operation.

Within the last four or five years the general surgeons have taken up abdominal operations for appendicitis with great enthusiasm, and, curiously enough, have gone over the same ground in working it out as gynecologists did about salpingitis and pelvic abscesses, discussing the well-worn question as to whether the local abscesses are intraperitoneal or extraperitoneal, whether to operate early or first try treatment, etc. Now the subject is so popular, and lately very fashionable and so well advertised, that most laymen who read the Sunday newspaper think they can give any of us points about appendicitis.

To-day, abdominal surgery is so popular and so commonly practised by nearly all medical men that it looks as though the gynecologists are going to be shut out altogether. In many of our largest general hospitals there are no gynecologists on the visiting staff, and, it is claimed, are not needed, for the gynecological surgery, abdominal and otherwise, is done by the general surgeons. It is a fact that some of the private hospitals of the gynecologists have been closed, apparently for want of material, while a large part of the surgery in the public hospitals done by the general surgeons is gynecological, especially the abdominal cases. It would be hard to find even in the smaller towns a young surgeon who is not doing more gynecological surgery than any other kind, and does not feel that he is fully competent to try his hand on all

[1] Read before the New York State Medical Society at Albany, January 26, 1897.

kinds of abdominal tumors. I have always said that for a gynecologist to make a practical success he must be a first-class surgeon. Now I say what is equally true, that for a surgeon to make a practical success of gynecological surgery he must be a first-class gynecologist. To make a diagnosis and decide what operation is needed, and to do some of the most important pelvic and abdominal surgery in the best manner, require a specially developed sense of touch that even very few gynecologists ever fully acquire in years by constant daily practice. In fact, gradually gynecological surgery has developed into a special art, which to do even fairly well one must inherit marked mechanical and artistic skill, or develop this artistic skill by prolonged persistent work as an apprentice under a master hand. Take a hundred young men who decide to study medicine and surgery; how very few of these one hundred could ever be trained to be successful sculptors, no matter how much they might study or know about how the work of sculptors is done, or even how much they may see others do? The same is true about special gynecological surgery. It is bad enough to do imperfect work in minor gynecology, in which, if a man understands and observes strict cleanliness, there is no danger to life; but when a human life, often of great value, hangs in the balance, those who cannot give the best chance of saving life should, it seems to me, hesitate and even stop work in such cases until they can be pretty sure of a good average success, if not the best.

If one operator loses only five per cent., another ten per cent., and another twenty per cent. or more in the same class of patients under like conditions, let us compare notes and find out why such a great discrepancy exists.

Nine years ago I stopped giving a full account of all my cases with results, because to me they sounded no longer new, and others seemed to be doing fully as well; besides, like all things of the kind, when once fairly under way, it soon began to be overdone, and all kinds of unsubstantiated figures of results began to appear in our most conservative journals. But now, since abdominal surgery has become so general in all directions, enough reliable and easily proven series of cases can be readily obtained to establish some fair standard, sufficiently close to indicate plainly what an operator's results should be to justify him in going ahead, or cause him to stop and improve his methods and give his patients a better chance to recover.

To do the best work in abdominal surgery, an operator must control a well-organized clinic, his assistants and nurses must be well drilled in his own methods, fully understand his ideas as to preparing the patients for operation, faithfully carry out the strictest rules of surgical cleanliness as to the patients, their own hands and persons, and all instruments and dressings, and observe the operator's views as to the after-care and treatment. To accomplish this, one must take time carefully to select and in some way manage to keep his assistants and nurses many years.

As our public hospitals are now conducted in New York City, where the house staff and nurses are changed every six months, the best-working clinic cannot be organized and kept up to a first-class standard. This fact will, in a large measure, account for the great difference between my results in Bellevue Hospital, where I have an average death rate of about ten per cent., and those in my private hospital, where the average is under two per cent. It is true that in Bellevue we get the very worst cases, and they are more liable to be complicated by Bright's disease and syphilis; but to-day a large percentage of private cases comes to me because they are difficult. If one has a private hospital, there is an advantage in getting most of his abdominal cases into it for operation; but there are some patients who will not leave their homes, and there are also many who should not be moved. I am satisfied that many cases of acute appendicitis are lost by being moved from their homes to hospitals. Take, for instance, a case of a distended and inflamed appendix or of local abscess in which rupture either has occurred or is about to occur; the moving makes rupture certain and also causes spreading of the septic material over the whole abdomen; and the time lost, even if it is only an hour or so, adds greatly to the shock and lessens the chance of a successful operation. The same may also be said of gunshot and stab wounds of the abdomen. I keep a handbag with all necessary instruments, dressings, etc., ready, and can at once pick it up and call an assistant and two nurses, and operate as soon as the patient is reached, wherever he may be; and if he is to be dragged over the streets to a hospital or his home, and it must be done, he can be moved at much less risk after the operation, when all pus and septic material have been thoroughly washed out.

Preparation of the patients for operation is of the greatest importance; even in acute emergency cases it is of great importance to empty the stomach and bowels as well as it can be done, without too much delay; or if the time is too short to use purgatives, to wash out the stomach and empty the lower bowels by injections before giving ether. When there is time, except when contraindicated, we move the bowels completely and give nothing—not even milk or broths—for twelve hours before the time of operating.

I am satisfied that the time and care I have taken, for many years past, in getting all my chronic cases ready for operations have greatly lowered my death rate, especially in very anæmic patients, such as those who have lost blood excessively, or have been weakened by repeated attacks of septic poisoning, or excessively fat women with weak hearts, etc. Gradually I have worked out a systematic plan of regulating the bowels and filling the blood-vessels with an approximately normal quantity of blood of good quality, for forty-eight hours or more before operating keeping the patient on a partly digested milk diet, and thus securing several hours before operation a clear and empty digestive tract, from the mouth to the anus, empty even of almost all gases for two or three hours before the time of operating. For many years we have entirely discarded the use of stimulants in preparing the patients, and rarely use tonics, but rely on simple laxatives and preparations of partly digested milk, such as peptonized milk, kumyss, fresh meat juice, and plain meat and bread. We give mild laxatives to regulate the bowels, and maybe a diuretic or antiferment when indicated. We can force the nutrition in this way, so that in ten days we can fill the pinkish lines indicating the veins in a pale and exhausted and anæmic woman with blue blood, and operate, feeling sure that she will not die of shock or heart failure if we happen to lose much blood during operation. When the bowels have had only milk diet for two or three days, and are well emptied two or three hours before operation, we are not afraid of opening or resecting an intestine, if it must be done during operation. For more than five years we have never faltered or desisted in pelvic or abdominal operations on account of adhesions, and all operations have been completely finished by removing all of the diseased organs or tissues, except in some cases of cancer, in which a pedicle could not be secured after enucleation or removal. I am fully aware that many operators will doubt the above statement, and think that I have not had bad cases of adhesions. In my tables I give the results of many cases in which the subjects had been previously opened and the abdomen closed on account of adhesions by other operators; I have reopened and

completed the operation so far in every case; in fact, in my private hospital a large percentage of my operations is in cases that have been pronounced inoperable by several other operators—even at Bellevue we have had some cases of the same kind direct from other hospitals. It is very generally acknowledged that one of the most formidable operations done on women is the removal of large multiple uterine fibromata, complicated by degeneration of the blood-vessels, salpingitis, and old adhesions of a more or less extensive peritonitis. The worst class of cases any of us have to operate on are those necessitating suprapubic hysterectomy. If you will glance over the three years' hospital work, reported in full in my tables, you will find, out of 343 abdominal operations, that 116 were suprapubic hysterectomies, mostly done for large fibromata; of 189 cases done in my private hospital, 80 were suprapubic hysterectomies, and all of the three deaths were among these.

Many years ago I would go to the country and operate on a patient, and make use of the family doctor and his nurse as assistants; but I found that this would not do, as my death rate for my outside cases was even larger than for those in Bellevue Hospital. Now, and for the past five years, I make it a fixed rule to send one of my own trained nurses several days ahead properly to prepare the case in my own way for the operation, and then go with my own assistant, operate, and leave my nurse; and in some cases one of my assistants remains till after the seventh day, when all danger is usually past. Since I have adopted this plan, if I could exclude the extreme cases of emergency, in which there is nothing to do but to operate at once, as the only chance to prevent immediate death, there would be very little difference between my death rates for outside cases and for those in my private hospital.

The cases given in the third table were all operated on in the City Hospital of Holyoke, Mass., by myself. They were practically outside cases, selected by others because they were difficult, and demonstrate what can be done without selection and without refusing any as inoperable. My first aim is always to adapt my operation to each individual case, and do the operation that gives me the best result—first, as to saving the life and, second, the future comfort and happiness of the patient. I have never yet become infatuated with any one method of operating in almost all cases, nor do I operate in all cases of a certain class by the vaginal route, nor in all of another by the suprapubic method. In double pyosalpingitis, if the adhesions and the indurated masses or tumors formed by the diseased appendages are low in the pelvis, or if the abscesses are not too large, I remove the whole uterus and all of both tubes and ovaries by the vaginal method. If there is necessity for it, or if there is any great difficulty in getting out all of the organs by the vaginal route, I may open the abdomen above to complete the removal or secure any bleeding vessels. In all cases in which the adhesions or masses extend above the brim of the pelvis, or if there are indications of the appendix vermiformis being involved, I operate from above. In almost all cases in which there is disease only on one side, or I wish to save some one or parts of both organs, I prefer the suprapubic operation. If the woman is young, under thirty-five, I am not willing yet always to remove the uterus merely because both tubes and ovaries must be taken out. In some cases I may leave the cervix uteri, so as to secure a longer and better vagina, and if necessary open the cul-de-sac to secure good drainage.

In cases of small fibromata of the uterus, in which the uterus does not exceed the size of a fist, I remove by the vagina when complete hysterectomy seems necessary in such cases. When they are large or badly complicated by high adhesions, I prefer complete suprapubic hysterectomy. When I can make a diagnosis of extrauterine pregnancy, I operate by the suprapubic method as soon as anything like a diagnosis is made, whether there seems to be hemorrhage or not. In all forms of peritonitis, when life is endangered, or a diagnosis of suppuration or formation of pus can be made, I operate at once before the case becomes hopeless from sepsis or by gradual extension of inflammation, or suddenly worse by rupture of the abscess. Even cases of extensive peritonitis may be saved by early operation, and almost all cases of local peritonitis and abscesses can be cured if operated on before great extension or rupture; and in unilateral salpingitis one tube and ovary may be saved by an early operation, that would certainly be lost by delay. Waiting for the fever to subside is like waiting for internal hemorrhage to stop, or for the patient to rally before opening the belly.

Results.—The death rate should almost always be given the place of first importance, and for a long time yet will be the crucial test for an operator in abdominal work. Quick and brilliant operations done in one's own pet and set way may be pleasing, but the best results will, as a rule, follow deliberate painstaking work in the hands of an artistic operator who readily and quickly adapts his methods of operation to the peculiar special characteristics of each case as he goes on with his operation, who never for a moment loses his temper, or gets rattled and forgets to carry out with absolute certainty all the rules of asepsis, and steadily keeps at his work till it is completely finished in all its details, even if he uses up an hour or more of time and tires out his audience. All a man needs to compel him to do his very best in every case of abdominal surgery is to keep always in his mind that an unconscious woman has given her life into his hands, and that failure on his part will cost a human life. Since making my last report of results in abdominal surgery nine years ago, in going over my records I find that I have reduced my death rate very decidedly, especially in those cases done outside of Bellevue Hospital, notwithstanding the fact that as I have grown older in the work worse cases have been sent me by my friends, and that many of the easy subjects of late are being attended to by doctors wherever they may be found. That is, as the operator becomes better known, he, like a consulting physician, is called on to see the worst possible cases, and the general run of his operations gives him a much larger percentage of desperate cases. I will confine my report of cases to all of those done within the past three years in my private hospital, in Bellevue Hospital, and a short series of cases that was collected for operation in the City Hospital of Holyoke, Mass., for the special purpose of having me go up and operate. My reason for excluding my private cases done outside in the homes of patients is that the statistics I give may be so exact and complete that they can be readily investigated and proven as correct. My private hospital was finished just nine years ago, and I have operated on more than five hundred abdominal cases there during the past nine years. My friend, Dr. George B. Fowler, of the health board, had the records of deaths searched for the names of all persons dying in 215 West Forty-third Street, the number of my hospital, and only nineteen were found. Since then one more has died. Two of these twenty were male patients, one of Dr. E. L. Keyes, and Dr. J. D. Bryant, who operated; and four of the others were not operative cases, leaving fourteen deaths after abdominal operations, giving a death rate of little less than three per cent. for all abdominal sections. So far, since I began to operate, I have never yet lost a case from a minor operation. In Bellevue Hospital the hospital records show that in the fourth division, in which is my service, the death rate

after all abdominal operations in my service is a little under ten per cent. In Bellevue, for several years past, about half the cases were operated upon by my assistant, Dr. R. H. Wylie.

I at first intended to give a list of all my cases, but I finally decided to give in detail only those done in hospitals where a regular record is kept of each case. Those done at Holyoke will fairly represent what I am doing in outside operations, which are not directly under my personal supervision. At the request of the managers and the medical board, I was invited to visit Holyoke every five or six weeks to do the important gynecologial cases to be selected by all members of the medical board. I offered to operate on any patient needing an abdominal operation and said I would like the most difficult cases that could be found in New England. For the past eighteen months I have gone to Holyoke ten times, usually going up Saturday night and returning Sunday night. In those ten visits I have done fifty-two gynecological operations, thirty-seven being abdominal operations, losing only one case. Some Sundays I did four or five abdominal sections, one after the other, stopping only long enough to wash my instruments as needed. At first I sent one of my nurses to prepare the subjects and remain to carry out the after-treatment; but after the third visit I trusted to the nurse of the hospital. I took with me to assist at operation only my first assistant or second assistant, or my own head nurse. Several members of the hospital staff, after the third visit, acted as my assistants in operating, and all members of the medical board rendered me every assistance in the most liberal and kindest manner.

Dr. R. H. Wylie has been my first assistant in most of my work for the past ten years, and now operates with about the same results as my own, as is shown in the Bellevue records. All abdominal sections done in my service are included.

Causes of Death.—1894: Two deaths. One was of a patient operated on by suprapubic hysterectomy for a large cancerous uterus; she died in third week after operation from acute insanity and exhaustion. She had been habituated to Hoffman's anodyne, and had symptoms of insanity before the operation. The second was also of a patient operated on by suprapubic hysterectomy for sarcoma of the uterus; she died in fourth week after operation, from apoplexy. The attack came on while she was sitting up.

1895: No deaths in private hospital.

1896: One death. Suprapubic hysterectomy for a large fibroid that had undergone calcareous degeneration. No signs of sepsis. Died suddenly on fourth day after operation. No post-mortem.

1896: One death at Holyoke. Suprapubic hysterectomy, also for fibroid that had undergone calcareous degeneration. No signs of sepsis. Died suddenly on fifth day. Post-mortem showed nothing about the wound or in the abdomen to cause death. Neither the heart nor the head was opened.

Deaths at Bellevue were mostly from sepsis.

Abdominal operations done in hospital practice for the past three years, beginning January 1, 1894, and ending January 1, 1897:

Total cases of abdominal operations	344	
Total deaths, of all cases	14	
Percentage of mortality		4.6

PRIVATE HOSPITAL.

Total of all abdominal operations done in three years	187	
Total of all deaths in three years	3	
Percentage of mortality for three years		1.57
Total suprapubic hysterectomies	74	
Total vaginal hysterectomies	45	
Ovariotomies and abdominal operations for appendicitis, etc	62	
Combined suprapubic and vaginal hysterectomies	6	

BELLEVUE HOSPITAL.

Total of all abdominal operations done in three years	121	
Total of all deaths in three years	10	
Percentage of mortality		8.25
Total suprapubic hysterectomies	25	
Total vaginal hysterectomies	11	
Ovariotomies and abdominal operations for appendicitis, etc	82	
Combined suprapubic and vaginal hysterectomy	1	

HOLYOKE CITY HOSPITAL.

Total of all abdominal operations done in the past two years	36	
Total of all deaths for the past two years	1	
Percentage of mortality		2.77
Total suprapubic hysterectomies	8	
Total vaginal hysterectomies	15	
Ovariotomies and abdominal operations for appendicitis, etc	13	

THE HYGIENIC, EDUCATIONAL, AND SYMPTOMATIC TREATMENT OF PULMONARY TUBERCULOSIS, WITH A PLEA FOR SANATORIUMS FOR THE POOR.[1]

BY S. A. KNOPF, M.D. PARIS, AND BELL. N. Y., NEW YORK.

FORMER ASSISTANT TO PROFESSOR DETTWEILER, FALKENSTEIN SANATORIUM, GERMANY.

In presenting to you a paper under this title I do not pretend to offer any new treatment, but simply wish to summarize the best of what I have seen and learned during a number of years devoted to the study of the treament of pulmonary tuberculosis, in American and European sanatoriums and health resorts. I will add to this a few remarks on recent experiments with Marmoreck's antistreptococcic serum as an agent in the symptomatic treatment of this disease.

Individual prophylaxis, diet, and education, which form the most important part of the hygienic treatment of consumptives, can, I believe in the majority of cases, be best carried out in the "closed establishment"—that is, in the sanatorium, where the patient is under constant medical supervision.

The first question which naturally arises is: Where should such a sanatorium be situated? It should be where it can do the most good to the largest number. I do not believe in the specific curative quality of any climate, but I do believe very strongly that it is essential to the majority of tuberculous patients to be treated and cured in the same climate where they will have to live and work after their restoration to health. I would therefore place the sanatorium for consumptives within easy reach of a large centre of population, at no greater distance than three to five hours by rail. It should be in a region known for its relative purity of atmosphere, where there is freedom from all miasmatic and malarial influences, and where the pathogenic microbes are found only in negligible quantities. If possible, it should be where the extremes of temperature are not too pronounced, and, if the region is a mountainous one, at an altitude of from one thousand to fifteen hundred feet. The site should be a pleasant one, with a southern exposure, and protected from the cold winds by higher mountains or woodlands.

The next question is: What kind of buildings should be selected for such an institution? The European system, under which they house as many as seventy-five to one hundred patients under one roof, or the American cottage system, with no more than four to eight in each cottage? To make so large an aggregation as one finds in some of the European institutions seems certainly not a good plan, since the hygienic measures are almost sure to suffer in such a house. On the other hand

[1] Read before the New York Academy of Medicine, January 21, 1897.

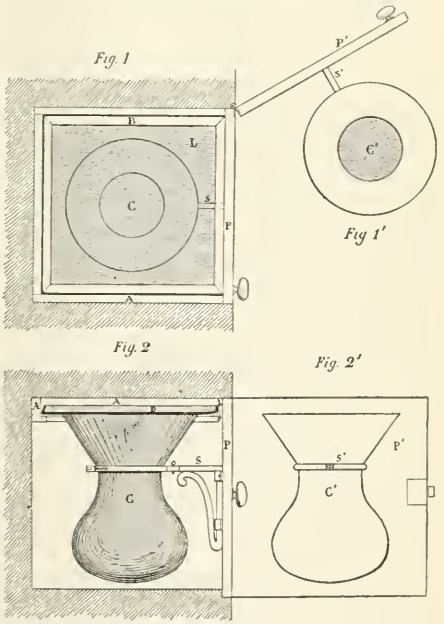
the cottage system, while it may be the ideal for some diseases, is, on the whole, not the most desirable as a sanatorium for consumptives. The constant medical supervision, one of the most important features in the sanatorium treatment, can hardly be carried out in a village of twenty or thirty small cottages several hundred feet apart, not to mention the increased expense which such a system involves. After having visited and studied some thirty odd institutions in this country and abroad, I endeavored in my French thesis on this subject[1] to illustrate what would seem, at least

Perspective View of a Sanatorium for Consumptives. Large Pavilion System.

to me, an ideal sanatorium for the treatment of patients suffering from pulmonary tuberculosis. It was designed by my friend, Mr. Van Pelt, of the École des Beaux Arts in Paris. I have adopted a plan between the European and the American, in other words, the large pavilion system. Three two-story pavilions, each accommodating twenty-five patients, are united by covered galleries one hundred feet long, which serve on rainy days as promenades. Behind the middle pavilion are situated the dining-room, kitchen, administration building, winter garden, etc., all united by galleries. At some distance from the main structures are a recreation pavilion, a house for visitors, and a place for isolation. Each main pavilion is about one hundred and thirty-five feet long, has twenty-five large well-ventilated rooms, also bathrooms, sitting-rooms, and parlors. In the basement are the hydrotherapeutic appliances. In front of each pavilion, along its entire length, is a veranda twelve feet wide, where the patients take their rest cure on their comfortable steamer chairs or lounges. Besides the ordinary hygienic precautions in regard to plumbing, heating, water supply, etc., all angles throughout the house are rounded to prevent the accumulation of dust. The walls are painted, that they may be easily disinfected; the floors are of hard wood, that they may be easily mopped, as sweeping or raising dust is absolutely forbidden in a well-conducted sanatorium.

One of the main features in regard to individual prophylaxis is the care taken with the expectoration and other secretions which might contain the bacilli. At the admission of the patient he is instructed that to expectorate anywhere except in a proper receptacle means danger to him and danger to others, for he may reinfect himself and communicate the disease to any number of other persons through the inhalation of the germs contained in the dried particles of his sputum carelessly deposited here and there.

Of course it is the duty of the administration of the sanatorium to see that a violation of the rules concerning the prophylactic measures is made impossible. Thus, there should be the proper kind of spittoons, a sufficient number of them, and a thorough destruction of the expectorated matter. But this should be done as unostentatiously as possible, for to see a countless number of all sorts of spittoons in various degrees of cleanliness is certainly not a pleasant sight for either patient or visitor. In my opinion, all spittoons standing on the ground should be done away with in a sanatorium, for while I am willing to concede to a certain portion of our American male population a wonderful dexterity in disposing of their buccal secretion, in the pure state or modified by the weed, I have yet to find a woman or young miss who knows how to hit the spittoon. Where much expectoration is going on one usually finds the brims of spittoons that are placed on the floor covered with dried sputum, and even the piece of oilcloth placed underneath as a precautionary measure often shows signs of the inexperienced spitter. To obviate these difficulties I have devised an arrangement of elevated spittoons, visible only when in use. In the walls of parlors, halls, and galleries, at appropriate distances, are placed small niches or cupboards three or three and a half feet from the floor. They are large enough to hold a spittoon eight inches high and about the same diameter, which is made of earthenware or colored glass, that its contents may be less visible, and is supported by a metal ring attached to the door of the cupboard. The patient desiring to expectorate opens the little door, thus bringing the spittoon within reach, and closes it again when he gets through. In the grounds the niches may be replaced by boxes mounted on stands. For the bedroom and the veranda, where the patient is taking his rest cure, the little covered white porcelain cups suffice.



Spittoon, elevated 3 ft. or 3 ft. 6 in. from the floor, and inclosed in the wall. *P*, door; *S*, hinged support; *C*, spittoon; *B*, cover. Figs. 1 and 1', plan; 2 and 2', elevation; Figs. 1 and 2 represent the door closed; 1' and 2' represent the door open.

Another prophylactic measure is the pocket spittoon, which the patient should always have with him to use when he cannot conveniently get at the others.

[1] "Les Sanatoria: Traitement et Prophylaxie de la Phtisie Pulmonaire," par le Dr. S. A. Knopf (Paris, Geo. Carré, éditeur).

One of the best of these is certainly the one devised by Geheimrath Dettweiler. It is a pocket flask about four inches long and six inches in its largest circumference. It is provided with a hermetically closing top and bottom, and is so constructed as to be easily cleaned. The touch of a spring causes the top to fly open to receive the intended deposit, and pressure of the lid causes it to close again with a snap. It would be perfection but that it is of glass and breakable, somewhat large and heavy, and its sharp protruding spring protector might cause an inoculation of the thumb. All these trifling disadvantages I believe I have overcome by having a spittoon made entirely of aluminum which weighs only three ounces instead of six ounces with nearly the same cubical contents.

All spittoons should be covered when not in use. The experiments of Spillman and Haushalter[1] have demonstrated beyond doubt the dissemination of the bacilli by flies. Patients in bed too weak to make use of the ordinary hand cup should be provided with moist rags, which should be burned immediately after use.

Dettweiler's Pocket Spittoon.

The best method of destroying the bacilli and their possible spores in the sputa collected in vessels seems to be the one recommended by Professor Grancher, of Paris.[2] The spittoons with their contents are placed in boiling water, the temperature of which has been raised by the addition of carbonate of sodium. The person intrusted with this work should be provided with strong rubber gloves, to guard against possible inoculation. Since the saliva of tuberculous patients not infrequently contains the bacilli, it is well to rinse the napkins in boiling water after each meal, or if for economical reasons this is impracticable, Japanese paper napkins may be substituted, which are to be burned after use. Knives, forks, spoons, glasses, etc., should also be washed in boiling water or sterilized after each use. The occasionally infectious nature of the saliva should also be a warning to consumptives never to kiss any one on the mouth. Patients should be taught not to use one handkerchief indiscriminately for the nose and wiping the mouth after expectoration. One should be kept in the pocket with the little flask to be used for the latter purpose. This may seem a superfluous precaution, and still I think the rather frequent coexistence of pharyngeal and laryngeal tuberculosis with relatively few advanced pulmonary lesions may well be explained by this mode of secondary infection, especially when we consider that the bactericidal quality of the healthy nasal secretion is probably always lacking in the tuberculous individual.

Consumptives should dress warmly, but not be so bundled up as to hinder their movements or make them perspire at the slightest exertion. Ladies will do well to adopt the Jenness-Miller system of dress reform, which does away with tight lacing and long and heavy skirts, thus facilitating abdominal breathing and freeing the viscera from the pressure caused by the usual mode of dress. Warm and dry footwear is essential. On very cold days the patients, while taking their rest cure, should be provided with hot-water bags or hot soapstones, to keep their feet warm.

[1] Spillman et Haushalter: "Dissémination du Bacille de la Tuberculose par les Mouches," Comptes rendus de l'Academie des Sciences.

[2] Grancher: "Maladies de l'Appareil Respiratoire. Tuberculose et Auscultation." Paris, Octave Doin, éditeur.

Under symptomatic treatment we must first direct our attention to combating the physiological poverty, the most striking symptom in pulmonary tuberculosis. This we endeavor to do by aerotherapeutics, good food and plenty of it, hydrotherapeutics, massage, and finally by medicinal substances to help build up the system, such as cod-liver oil, phosphates, strychnine, iron, creosote, bitter tonics, etc.

By aerotherapeutics is meant the gradual exposure of the patient to the open air until he virtually lives in the fresh air, winter or summer, rain or shine. This is what the Germans call the "Dauerluftkur." The patient is placed on the veranda, comfortably wrapped up on his lounge or steamer chair, in a position to admit of a complete muscular relaxation. Every half-hour or so he rises to take his breathing-exercises. I am willing to acknowledge that I think them of much greater importance than do the majority of phthiseo-therapeutists. It is true that whenever there are old pleuritic adhesions these strong respiratory movements may become painful, owing to the tearing of some fibrinous bands, but this is salutary and not lasting. The respiratory muscles become developed, the increased pulmonary function makes the process of hæmatosis more complete, and helps to dissolve the mucus and aid in expectoration. This is the little system of exercises I have adopted: The patient, who is taught always to breathe through the nose, takes a deep inspiration slowly, while raising the arms from the sides to a horizontal position, holds the breath for a moment, and lowers the arms during the expiration, which should be somewhat more rapid. The second exercise is like the first, except that the upward movement of the arms is continued until they meet above the head. In the third exercise the patient stretches his arms out as in the position of swimming, the dorsal surfaces of the hands touching each other. During the inspiration the arms are moved outward and finally meet behind the back. They are brought forward again during the expiration. Each respiratory act should be followed immediately by a secondary forced expiratory effort. This is for the purpose of expelling as much of the supplemental air as possible, and may be effectually aided by supinating the arms and pressing the thorax with them. The feebler patients must content themselves with breathing-exercises at rarer intervals and without rising from the bed or couch, and of course without moving the arms. Patients able to walk alternate their rest cure and breathing-exercises with graduated promenades, that is to say, walks on paths varying in inclination from one foot in three hundred to one foot in sixty feet.

Patients are taught never to hurry, always to stop before getting tired, and never to exercise to the extent of perspiring. Should they at any time have neglected this precaution and perspire profusely, they should at once return to the house, be rubbed off, and go to bed. While out of doors on cold or windy days consumptives should keep their mouths closed, and talk as little as possible. These precautions are essential to protect the patient from colds, which are always to be dreaded in consumption. In the recreation pavilion, parlor, library, or anywhere else, the air must always be kept fresh and pure. Of course the patients always sleep with an open window, wide open in summer and partly so in winter or on stormy days. But, however intelligent the patient may be, none of these measures must ever be left to his caprice; everything—rest cure, breathing-exercises, walks, even how far the window should be open—must be regulated by the attending physician.

Hydrotherapeutics, beneficial and indispensable as they are, must be applied most judiciously. The patient is educated up to the classic douche by preparing his skin first by dry friction only. Later the

patient is rubbed for a time with alcohol, then with equal parts of alcohol and water, then with water alone, and finally he receives the affusions or douches according to indication. Lateral weak douches or affusions may be advantageously applied to loosen old pleuritic adhesions. It goes without saying that the douche apparatus is always manipulated by the medical attendant.

The diet of tuberculous patients should be varied and abundant, and their meals served regularly and in an appetizing manner. They should be urged to eat, and it should be impressed upon them that their digestive powers are far greater than their appetite indicates. They may have no desire for food whatsoever, and yet they can eat and assimilate a good deal. Every consumptive must be told that upon his willingness to eat depends his salvation. Feverish patients should eat when their temperature is lowest. Milk from tested cows, butter, cream, should be taken in large quantities. The only precaution necessary is to take the milk in small sips, and as many as eight or ten glasses may be taken per day. The patient's teeth should be kept in good condition; he should eat slowly and chew his food well. Any indigestion should be reported to the doctor at once. For constipation an increased proportion of fruit often suffices; if not, abdominal massage or cascara or some other mild laxative may be resorted to. Diarrhœa, if not due to tuberculous lesions, should be treated by first cleansing the intestinal canal and then giving appropriate diet, such as rice, eggs, toast, cocoa, mucilaginous soups, Bordeaux with arrowroot. If of tuberculous origin, the usual treatment by opiates and astringents must of course be pursued.

Painful coughs seem best relieved by codeine solutions; but cough as a matter of habit, when there is nothing to expectorate, should be suppressed by discipline. Dettweiler tells his patients that to cough in public without cause is scratching the throat because it tickles, and that it is as ill-mannered as scratching one's head in public when it itches. On the other hand, I think it just as essential to warn the patient never out of false delicacy to swallow his expectoration and thus infect his intestinal tract. Sips of cold milk will help to overcome tickling sensations in the throat until the patient has fully become master of his cough.

Hæmoptysis is treated in sanatoriums as anywhere else—absolute rest in a half-sitting posture, ice bags over heart and apices, ligation of upper and lower limbs, morphine, ergotine, etc. The physician will of course assure the patient that he need not be alarmed, as hemorrhages are ordinary phases of the disease, not necessarily lessening the chances of recovery. Timid patients who have never had hemorrhages should even be warned that this may occur.

To combat night sweats the patient is given a glass of cold milk with one or two teaspoonfuls of cognac just before retiring. In cases in which this and even the atropine, agaricin, etc., failed, I have often succeeded by applying a wet pack in the form of a shawl over chest and apices.

Counter-irritants are to my mind valuable adjuvants. They draw from the delicate lung structure countless dangerous micro-organisms into the less delicate cellular tissue, where by the action of the counter-irritant the number of the phagocytic white corpuscles has been increased; and thus an actual destruction of pathogenic microbes is brought about by the simple mustard plaster, the old-fashioned dry cups, or the *points de feu* (ignipuncture).

One of the most surprising things to me which I noticed in my studies of the sanatorium treatment, especially in institutions situated in higher altitudes, was the almost total cessation of the fever of many of the newly arrived consumptives after a few days, without the administration of any antipyretic whatsoever. The only explanation to me was the almost total absence of pathogenic microbes, especially the streptococci, in these higher altitudes, and consequently a cessation of the association of microbes. This conclusion led me to my experiments with Marmoreck's antistreptococcic serum.[1] I wrote to the Pasteur Institute, and received my first lot of serum last June. Through the courtesy of my distinguished teacher, Professor Biggs, I was first allowed to test the antistreptococcic action in our city laboratory by a series of experiments on animals. These experiments were satisfactory enough to justify the employment of the serum in the human species. I will rapidly summarize the results I obtained, speaking, of course, of consumptive cases only. The action of the serum was not always uniform. With patients whose temperature rose over 102° F. for several days, I did not obtain any results. When, however, there was a temperature of only 101° F., or a trifle over, with streptococci in the sputum, a first injection of ten cubic centimetres reduced the temperature from one to one and a half degrees. A second of ten cubic centimetres brought it down to nearly normal. A third, fourth, fifth, and sixth of five cubic centimetres each, given first every twenty-four hours, then at longer intervals, helped to maintain the normal or nearly normal temperature, and a general better feeling was experienced by the patient.

Dr. Weaver claims still better results.[2] Among other cases he reported one in the *Journal of the American Medical Association* of September 5th, with a temperature of 105° F., which he brought down to nearly normal with a single dose, and maintained it there by repeating the injection every second day. However, I think it will require much more experimentation to fix the real value of this serum. Its action seems to depend not only upon the make of serum used,[3] but also upon the degree of virulence of the toxins produced by the streptococci in the system. The earlier the injections are made the better seem the results. I should like to encourage its use in pulmonary tuberculosis whenever there is a mixed infection, and when after a short trial absolute rest, fresh air, and the usual antipyretics have failed. I am happy to be able to announce that our very efficient city laboratory is now busy at work to obtain this serum, and hopes soon to be able to furnish you with sufficient quantities, and then you may try its merits for yourselves.

The mind of a consumptive should be treated as well as his body. He must not have time to think of anything but getting well. At all hours of the day he must have something to do with that purpose in view. At this hour his meals, at this his rest cure, at that his walks, at another his douches, etc. Cheerful reading, quiet games, occasional entertainments, or little lectures on hygiene should form the pleasant features of sanatorium life. Some consumptives are sanguine, some despondent, some irritable, and most of them imprudent—"Ein leichtsinniges Völkchen" ("a careless little lot of people"), as Dettweiler calls them. Much tact and forbearance, combined with a never failing firmnesss when occasion demands, are necessary to deal with them effectually.

To say that these various phases of treatment just described can be carried out only in a sanatorium would be foolish. They can be carried out by any physician in private practice whose patient is willing,

obedient, and so situated as to have all the comforts and the surroundings which the hygienic and dietetic treatment demands. But how many of these patients have we? Are not the majority of tuberculous patients poor? And is it not utterly impossible to treat them successfully in their unhygienic homes or even in our general hospitals? It is for these poor consumptives that I plead for the creation of sanatoriums.

To demonstrate the necessity of such special institutions allow me to picture to you in brief the life of a consumptive before and after his admission to one of our general hospitals.

The honest laborer who has the misfortune to become tuberculous, and finally phthisical, will at the onset seek the advice of his family physician. Presuming that a correct diagnosis has been made, the physician is likely to prescribe, with the usual remedies just then in vogue, also a few weeks of rest. This, under the most favorable circumstances, means a consumption of part of the savings. After a while the patient, seemingly improved, resumes his former occupation. But the improvement is not lasting. He is again and again obliged to take a rest. The intervals between the periods of work become longer and longer. Instead of the physician the nearest dispensary is visited, for there has been too great a drain already on the little capital put aside during better days. At last, unable to work at all, he stays at home until he is forced to seek admission to one of the public hospitals.

A large number of our general hospitals supported by private charity absolutely refuse all patients suffering from tuberculosis, and it is but natural that the attending physicians of our general municipal hospitals should also avoid crowding their wards with tuberculous patients, especially if there is a likelihood of a very prolonged stay. Thus the consumptive often obtains admission with difficulty. Finally admitted, he is placed in one of the general wards. His neighbor to the right may have typhoid fever, the one to the left a pleurisy *à frigore;* opposite him may be a rheumatic or a fellow consumptive. If the physician in charge is in favor of medication, the patient will receive the latest remedies well spoken of in the treatment of tuberculosis. If the doctor is sceptical as to the value of medication in this disease, the patient may or may not receive the special diet, and the rest is left to nature. In the morning before the arrival of the visiting physician, the poor consumptive inhales the dust, and with it countless numbers of pathogenic microbes, raised by the attendant sweeping the ward with an ordinary broom instead of wiping the floor with a moist mop. If the patient has not yet his mixed infection he will soon get it. Instead of passing most of his time in the open air, the consumptive in our general hospitals is almost totally deprived of this essential factor in the proper treatment of his disease. Should he day or night ask to have a window open, his rheumatic neighbor would very strenuously object, for he could not stand the draught. Respiratory exercises are but rarely recommended, for the physician knows that they are useless in the ordinary hospital atmosphere. At meal times the consumptive patient eats but little. The frequent anorexia he cannot overcome, and even the special diet does not tempt him. The aerotherapeutic and hydrotherapeutic measures, so largely and beneficially resorted to in sanatoriums to overcome the loss of appetite, cannot be carried out in a general hospital. At night the patient sleeps but little. He is either kept awake by his own cough or that of his neighbor. The stuffy night atmosphere of the ward furthers still more his hyperidrosis. Thus he passes weeks, sometimes months, until a fatal determination ends his sufferings; for these patients rarely enter the hospital in time even to hope for a lasting amelioration. And during this time the family, deprived of its natural supporter, is most likely to have become a public charge.

And how does the presence of the consumptive in the general hospitals affect the other patients suffering from acute diseases? Leaving aside the depressing mental effect upon these patients, we know that it is next to impossible to have such thorough hygienic and prophylactic measures in a general hospital as are characteristic of the sanatorium. Is not the patient with his pleurisy *à frigore* in great danger of having his acute infection transformed into a chronic tuberculous one? And the typhoid-fever patient, with his greatly reduced power of resistance—may he not also become the prey of the bacillus tuberculosis ever present in our general hospitals?

The medical and sanitary advantages which would be obtained by the creation of municipal sanatoriums for consumptives are evident, but these are not all. The patient with incipient phthisis, after a few months of practical training in the sanatorium, will have learned how to take care of his expectoration to avoid auto-infection or the communication of his disease to others. He will have learned how to avoid the causes which may aggravate his condition and acquired such hygienic habits as to have the best chance to become and remain entirely well.

But sanatoriums do not serve only as educators of individuals but as educators of communities as well. In the villages where the two largest German sanatoriums are situated, Goerbersdorf [1] and Falkenstein,[2] the mortality from tuberculosis has actually decreased among the village people, being now one-third less than before the establishment of those institutions. This, no doubt, is due to the example set by the inmates of the sanatoriums, and it is also the best proof that well-conducted sanatoriums for consumptives are not centres of infection, but, on the contrary, places where one is safest from contagion.[3]

Experience abroad, where there are some sixty odd sanatoriums, half of them for the poor, already in operation or in course of construction,[4] has demonstrated that the running-expenses of a well-equipped sanatorium for consumptives are little or no greater than those of the general city hospitals; and statistics show that the same would be the case in New York. The daily expense per capita in the seven most important hospitals under the administration of the department of public charities and correction is as follows:

Fordham Hospital	$2.0626 [5]
Gouverneur Hospital	1.8399 [5]
Harlem Hospital	1.6919 [5]
Colored Home and Hospital	1.00 [6]
Bellevue Hospital	0.7742 [5]
Ward's Island Hospital	0.42 [6]
City Hospital	0.3338 [5]

This gives us an average of $1.16 per day, and the daily average expense for each tuberculous patient at the Adirondack Cottage Sanatorium, one of the most successful institutions in this country, is only $1. The least favorable results obtained in sanatoriums devoted exclusively to the treatment of consumption are as follows:

14 per cent. absolute cures;
14 " " relative cures;
42 " " ameliorations.

[6] Obtained in answer to personal inquiry

Thus, through the establishment of municipal institutions for the treatment of the curable tuberculous cases and for the isolation of the hopeless ones, the commonwealth would be the financial gainer in the end. Thousands of dollars are now expended for tuberculous patients in general hospitals, where, in spite of the best intentions on the part of the medical staff, they cannot be treated, but only kept, and are at the same time a constant menace to the other patients suffering from acute diseases. For the same expenditure a goodly number could be cured and centres of infection forever done away with. We all would be benefited in sanitary as well as social respects, could we give to the honest laborer above referred to the same chance (twenty-eight per cent.) of becoming again a well man, a bread-winner, and a supporter of his family. To attain this noble end let us create sanatoriums—create them soon and create them well.

349 West Fifty-Eighth Street.

STRANGULATED CÆCAL HERNIA, OF ONE HUNDRED AND FIVE HOURS' DURATION, IN A WOMAN AGED SIXTY-SEVEN YEARS.[1]

By JOHN B. WALKER, M.D.,

Assistant Surgeon, Hospital for the Ruptured and Crippled; Lecturer on Hernia at the New York Polyclinic.

About thirty years ago, while in good health, the patient suddenly began to have pain in the right side. Appendicitis developed; the abscess pointed and broke spontaneously beneath Poupart's ligament in the region of the femoral opening. It closed in three weeks. A year later a small lump began to appear in the region of the scar, just below the fold of the groin. This slowly increased in size and later was diagnosed as a femoral hernia. A truss has been worn at times, and as a rule has retained the hernia; at times, however, the hernia has slipped down underneath the pad of the truss. On several occasions the hernia has been apparently irreducible, but after twenty-four to thirty-six hours of rest in bed, together with applications of ice, it has been reduced. Her general health remained good.

On Friday morning, October 23, 1896, after continued straining at stool, the hernia came down and resisted all efforts at reduction. She worked about the room during this day, but the following day (Saturday, the 24th) she remained in bed and tried repeatedly to reduce the hernia, but without success. Her bowels did not move and she had some pain in the hernia. The next day (Sunday, the 25th) she applied hot fomentations, but again failed at reduction. She took but little nourishment (milk and tea), and was restless at night.

Monday, the 26th, she called in a physician who (after trying taxis without success) pronounced the case one of strangulation, and advised prompt removal to a hospital for operation. She refused, and he departed. The same afternoon she began to vomit and the pain increased.

Tuesday, the 27th (the fourth day), she became rapidly worse, the vomiting becoming fæcal and the distention also increasing. At 6:30 P.M. the writer saw her. Her face was pinched and anxious, and showed every evidence of the marked prostration and weakness which the lack of nourishment, the prolonged pain, and the loss of sleep had produced. The abdomen was greatly distended and everywhere tympanitic; the legs were drawn up and could not be extended; in the right femoral region a tense, tender, hard, non-fluctuating, irreducible tumor, the size of an orange, was found. There was no impulse on coughing. The pulse was 120, small, irregular, and weak; temperature, 99.5° F.; respirations, 24. The tongue was coated, dry, and brown. There was no hiccough. The vomitus was stained with bile, and had the fæcal odor of the contents of the small intestine. Obstruction was complete and no gas passed. The pain radiated over the lower portion of the abdomen and was colicky in character.

She was removed to the hospital and at once placed in a full-length tub bath. At first the water was just a little warmer than she desired, but after ten minutes she said she felt much easier. The bath was continued about fifteen minutes, when she was taken out, rubbed thoroughly dry, wrapped up in blankets, and put to bed. Eight minims of solution of Magendie were given hypodermatically, and she rested quietly for fifty minutes. (The groin area had been antiseptically prepared for operation as soon as she had left the bath.) An imaginary curved line (about four inches long) was drawn from the spine of the pubis upward, outward, and downward, over the tumor, and along this line was injected twenty minims of a four-per-cent. solution of cocaine. The skin was very thin and the sac was quickly opened (the bowel was nowhere adherent to the sac). It contained about three ounces of a reddish-brown serum with a foul odor. No fæcal particles were present. The color of the bowel was reddish-brown, with some darker, almost black areas. It was somewhat marbled in appearance, lustreless, and did not readily bleed when pricked. The constricting ring was very close and firm, so that it was not possible to insert even the tip of the little finger. A curved director was then carefully pushed alongside the bowel at its inner side, underneath Gimbernat's ligament, close to the spine, and on this as a guide the tip of the knife was carefully pressed against the tense fibres in order just to nick them (but not to push with much force to cut through all the fibres at once). A few fibres yielded and so allowed the tip of the little finger to be inserted, and upon this as a more intelligent guide Poupart's ligament was cut upward and inward, making the entire opening into the abdomen about one and a half inches in diameter.

There was no especial bleeding from the incisions. The bowel was carefully examined at the seat of constriction and no wound was discovered; but there was a deep indented furrow, one inch long, where the ligament had constricted the bowel; there was no ulceration. The protruded mass was drawn down out of the canal as far as possible and gauze packed about its neck to prevent anything re-entering the abdominal cavity. The protrusion consisted of about three inches of the head of the cæcum with the vermiform appendix, six inches of the ileum, and a tongue of omentum. (The appendix was three and a quarter inches long, one-quarter inch in diameter, with a short mesentery.) These different portions were united by adhesions, which were not dense and which were easily separated without much bleeding. About twelve inches of the ileum above the constriction was withdrawn from the abdomen and carefully inspected. The portion above the constriction seemed to be in good condition, while that below seemed almost gangrenous. It was hoped that this might improve, so the entire mass was covered with hot dry gauze. The gauze was removed in ten minutes, but the color and general condition, of the bowel had not improved. It was not safe to reduce the loop which seemed gangrenous, and she was too weak to stand an anastomosis or resection. So there remained the very faint chance that the vitality of the bowel might later improve, now that the constriction was relieved, if the loop outside the body could be kept at the body temperature. It seemed best (to save time) thoroughly to protect the intestines

[1] Read before the surgical section of the New York Academy of Medicine, January 11, 1897.

with a mass of gauze and cotton and to return her to bed at once. She was in bed thirty minutes from the time the cocaine was injected. She had very little pain at the operation, except when the arterial walls were clamped (this being due to the pressure on the sympathetic-nerve fibres). Special care had been taken to keep the patient warm, and the operation was not accompanied by any shock. She was placed in bed at 11 P.M. and given five minims of solution of Magendie. Her pain ceased; she passed gas three hours later; she vomited only twice, and was much easier the next morning (the 28th) at eight o'clock. The bulky dressing was then removed and it was found that the condition of the intestine had somewhat improved; fresh hot dry gauze was then reapplied. During the day teaspoonful doses of hot water were given by the mouth very often, but no other nourishment. One-sixtieth of a grain of strychnine and one-two-hundredth of a grain of digitalin were given every four hours. The rectum was washed out and an enema of one ounce of whiskey, two ounces of chicken broth, and two ounces of peptonized milk was given every four hours.

At 3 P.M. the dressings were removed, and the condition of the bowel had so much improved (although there were three small dark, almost black areas in the mesentery) that it seemed best to reduce the protrusion. Gas circulated and passed frequently from the anus. The distention was much less, the intestinal walls were lax and had fallen together; the walls and the mesentery had become very much infiltrated and thickened with serum. Reduction was accomplished with some difficulty; the upper part was very gradually pressed back, a little at a time, while the edges of the wound were separated by retractors. After every portion had been reduced, a large amount of narrow sterile gauze was packed around the loop of suspected intestine (so as to shut it off from the general peritoneal cavity in case there should be any suppuration). The ends were brought out into a large gauze dressing, wet with aluminium acetate and covered with a rubber protective.

October 29th. She rested much better during the night, retaining the enemata and taking some peptonized milk by mouth. The dressing was so saturated with serum that it was necessary to change it every six hours. A soap suds and turpentine enema was given through the high rectal tube and was very successful.

October 30th.—Continued improvement; dressing changed four times; enema every four hours, and increased nourishment by mouth.

October 31st.—Bowels move satisfactory; a little gauze removed.

November 10th.—The gauze was gradually pulled down until the last piece was removed to-day. The dressing is changed morning and evening; the opening into the abdomen has contracted down to one-half of an inch in diameter. The sac has sloughed out, leaving a small granulating area.

November 25th.—The wound has entirely healed. A truss is worn, and she walks about the ward a well woman.

Arteriosclerosis.—This is a disease of the arteries, characterized by a thickening of their walls, due to a deposit in the intima, with a diminution in the size of the lumen. The disease may be separated into three divisions: 1. The nodular or arteriosclerosis nodosa, in which the disease is circumscribed, although it may be widely distributed. 2. Senile, in which the change in the arteries is one of the signs of advancing years. 3. General arteriosclerosis, a disease of the middle aged or young, and which is the form to which reference is made when the disease is mentioned.—*Boston Medical and Surgical Journal*, December 10, 1896.

ON THE PREPARATION OF BLOOD FOR MICROSCOPICAL EXAMINATION (SECOND PAPER).

By HENRY G. PIFFARD, M.D.,

PROFESSOR OF DERMATOLOGY IN THE MEDICAL DEPARTMENT OF THE NEW YORK UNIVERSITY.

My first paper on the subject, published in the MEDICAL RECORD for October 17, 1896, has brought me a mass of correspondence. Some writers have thanked me for the information contained in the article, and others have asked for additional light on the subject. Some, indeed, say that they are utterly discouraged, as they cannot get the results described in the text-books and have not been able to discover the causes of failure. A few gentlemen have called at my laboratory to see just how the procedures were carried out; and some criticisms have been made regarding the technique that I recommended.

One gentleman asks: "Why do you advise making a cover-glass film instead of spreading the film directly on the slide?" I answer, because the image is clearer and sharper when the objects under examination (the blood cells) are in optical contact with the cover than when they are separated from it by a medium, especially air.[1] Every microscopist has, or ought to have, one of Möller's test slides of the Pleurosigma angulatum mounted dry, as it is perhaps the best single object with which to test the quality of a lens of medium or high power. If he will look carefully over the slide he will find here and there a valve, the central portions of which are attached to the glass (by melting in), while the extremities have air between them and the cover. The superior image of the central parts should prove an object lesson of value. Let the experimenter then examine one of Möller's balsam mounts of the same diatom, and compare the image with that of the dry mount. A good one-fourth inch objective will show the markings beautifully on the dry diatom, while they will only with difficulty be seen on the one mounted in balsam. Such an examination will emphasize the statement made in a previous paper, that blood covers show, in general, to much better advantage when mounted dry than in balsam.

It has been objected, however, that details in the nuclei of leucocytes can be made out better in balsam mounts. This is true—the chromatin deeply stained with methylen blue is opaque, and its outlines appear sharper and more distinct when surrounded by the medium of higher index. The index of balsam (1.52), however, is low, as compared with those of other utilizable media. If the covers be examined in oil of cinnamon (Cassia), the index of which is 1.59, there is a distinct gain over balsam. Still better are my "naphthalinambar" (n. 1.625)[2] and the pure monobromide of naphthalin (n. 1.65). The oil of cinnamon, however, should be on the table of every working bacteriologist and hæmatologist. The iodide of methyl (n. 1.72) may also be employed to advantage in special cases. It is extremely volatile, however, and the cover must be instantly sealed with a good cement—either shellac or Bell's. The iodide extracts some of the basic stains, but appears to have little effect on neutral red.

[1] Since the above was written I have received a copy of Van Heurck's "Treatise on the Diatomaceæ." In this he quotes Prof. Hamilton L. Smith, as follows: "For mounting diatoms I invariably place a drop of the liquid containing them upon the cover, never on the slide, . . . for the diatoms thus treated when mounted appear much sharper and cleaner." Van Heurck adds: "I entirely agree with Professor Smith in his opinion." It may be objected that we are not dealing with diatoms but with blood cells, to which I reply that we are dealing with universal optical laws, to whose authority we must yield, as they will not be modified to suit our convenience.

[2] MEDICAL RECORD, May 4, 1895. "Naphthalin-ambar" can be prepared according to my published directions, or may be procured from Eimer & Amend, of this city.

Another source of trouble is in the use of methyl blue. Probably one of the best articles in the English language on the subject of blood that has recently appeared is to be found in Volume VII. of Wood's "Twentieth Century Practice." The author of the article repeatedly directs the use of this substance in his staining fluids. I am not surprised that those who have followed these directions have come to the conclusion that blood staining is a delusion and a snare. Methyl blue is the sodium salt of triphenylpararosanilin-trisulphonic acid. It is a diffuse plasmatic stain, staining protoplasm and nucleus uniformly. It belongs to Ehrlich's group of acid stains, and behaves, except as to color, like eosin.

The proper substance to use is methylen blue. This is the chloride of tetramethyl thionin. It belongs to Ehrlich's group of basic stains, and gives sharp nuclear differentiation. An impure preparation contaminated with zinc costs about five cents a gram, and is the one commonly used. The pure article, costing about four times as much, gives a sharper and cleaner stain.

Dr. Waldstein, in a paper read before the New York Pathological Society,[1] highly recommends thionin as a basic stain, but says that there is some difficulty in procuring a good preparation. After trying several sorts, my experience leads me to prefer that made by Cogit, of Paris. It can be obtained from Queen & Co., of Philadelphia, or at their New York office, 116 Fulton Street. Da Costa, referring to this preparation, recommends the following formula:

Distilled water	90
Alcohol, 95 per cent.	10
Carbolic acid, 25 per cent.	1
Thionin	0.5

This certainly gives an admirable nuclear stain, and displays the crescent and endoglobular plasmodia in the finest manner.

Some fail to make a satisfactory double stain with eosin and methylen blue. None of the text-books, so far as I am aware, specifically directs the kind of eosin to be employed. There are in the market several sorts, some of which will not contribute their quota toward the desired result. They stain the corpuscles strongly when first applied, but when the basic stain has acted and been washed off, the eosin is no longer apparent. The proper eosin to use is Grübler's, marked "soluble in alcohol."

A very beautiful but little known basic or nuclear stain is one furnished by Grübler under the name of neutral red. Nuclei, and other bodies with the same chromatic affinities, respond to it perfectly. It may be used in one-per-cent. aqueous solution. The same substance may be used for *intra-vitam* staining. Living infusoria and even minute vertebrates, such as the young tadpoles of the frog or the newt, stain with it quickly and without apparent injury to their functions.

There are two stains mentioned in the books, however, with which I must confess I have had but little success. These are Ehrlich's "tri-acid" and Chenzinski's neutrophil solutions. I have purchased the Ehrlich stain prepared by Grübler, and have several times made it up myself in accordance with the following formula:

(A)	Distilled water	100
	Orange G	15
(B)	Distilled water	100
	Absolute alcohol	100
	Acid fuchsin	65
(C)	Distilled water	100
	Absolute alcohol	100
	Methyl green	125
(D)	Glycerin	100

[1] MEDICAL RECORD, September 12, 1896, p. 385.

Make the solutions separately, and then mix all together.

Chenzinski's solution is made as follows:

Methylen blue, saturated aqueous solution	40
Eosin, one-half per cent. in seventy per cent. alcohol	20
Distilled water (or glycerin)	40

I trust that others have had better success with these solutions, and if so, that they will make known their exact technique.

Various solutions have been prepared for the permanent preservation of blood cells without apparent deformity of their contours. The best known of these, perhaps, is Hayem's "Solution A," composed of the following ingredients:

Distilled water	200
Sodium chloride	1
Sodium sulphate	5
Mercuric chloride	0.5

An ounce of this solution is taken in a small beaker. The end of the finger is then freely punctured and immediately plunged into the liquid, so that the blood may flow into it without contact with the air. Five or ten drops are sufficient. Human and all other kinds of blood that I have experimented with keep well in "Hayem." The corpuscles sink to the bottom, but when shaken up diffuse uniformly through the liquid, and a drop may be withdrawn for examination. If it is desired, however, to make a stained cover-glass preparation, the corpuscles must be washed several times with dilute alcohol and distilled water, to remove the mercuric salt.

I have devised another solution, which answers admirably for the blood of batrachia and of birds, but does not always preserve human blood in a satisfactory manner. It is composed of:

Distilled water	95
Formalin	5
Sodium chloride, c. p.	0.75

Permit one or two per cent. of the blood to flow directly into the solution, and pour the mixture into a vial. In a few hours the blood is completely fixed, and a drop of the mixture may be withdrawn for examination. If you desire to prepare stained covers, put a drop of the fluid on a cover glass and evaporate to dryness at a gentle heat. When dry, apply the stain and manipulate just as you would an ordinary cover. The salt crystals disappear with the first washing.

I have been asked by several where a good turntable could be had. Up to within quite a recent period I could not have answered this question, but at present am glad to say that the "self-centring" table as *now* made by Bausch & Lomb is in every way satisfactory.

Whether blood should be fixed by heat or by alcohol deserves a moment's consideration. Some advise that the cover be placed in absolute alcohol, or a mixture of this with ether, for about ten minutes. This I have never found satisfactory, but if the covers be left in the mixture for two hours or more, very good results may be obtained. On the whole, however, I prefer fixation by heat, as originally recommended by Ehrlich. To accomplish this most conveniently, I use a simple apparatus. It consists, in the first place, of a small electric stove, about four and one-half inches in diameter.

If attached to the Edison one-hundred-and-twenty-volt current, the surface of the plate will, in ten minutes or less, reach a temperature of about 350° C. This heat is excessive for our purpose, and must be controlled by a rheostat.

A small drying-oven with a shelf completes the apparatus. When it is first set up, it is necessary to use a thermometer to adjust the rheostat. In my own

apparatus the temperature of the oven gradually runs up to about 120° C. in three-quarters of an hour, and afterward remains at that point indefinitely.

This stove may, of course, be used for many other purposes, the heat being regulated to any point within the maximum with the rheostat.

This apparatus is not at the present time for sale in a complete form, but I have no doubt that dealers would be pleased to supply it, and could do so with reasonable profit to themselves for about twenty dollars, which price should include stove, rheostat, connecting cords, oven, and thermometer.

I cannot close this paper without calling attention to the recently published book by Dr. Cabot on the "Clinical Examination of the Blood." He has but little to say concerning microscopical technique, but, viewing the subject from its clinical aspects, has given us a work that in my judgment is the best that has yet appeared in any language.

Clinical Department.

REMOVAL OF A TUBO-OVARIAN ABSCESS (LEFT) AND AN OVARIAN CYST AND TUBE (RIGHT) BY ENUCLEATION, WITHOUT LIGATURE, CLAMP, OR CAUTERY.

By J. COPLIN STINSON, M.D.,

San Francisco, Cal.

The history of the case I shall report is of some interest, as there were numerous adhesions of the adnexa and the uterus to the surrounding viscera and as the appendages were removed by enucleation, without ligature, clamp, or cautery.

Mrs. R. C——, aged forty, the mother of two living children, had always enjoyed good health up to a few years ago, when she began to run down, lost some flesh, became pale and somewhat anæmic, and inclined to be nervous; the bowels became very constipated; the patient commenced to have considerable vaginal discharge, and later on pain in the lower part of the abdomen. While under the care of one physician she was given the rest cure, massage, etc. This treatment was continued for a week or so, when she would no longer remain in bed. She went along, complaining mainly of nervousness, with at times pains over the heart; constipation, for which she took freely aromatic cascara sagrada; a continuous vaginal discharge; and pains occasionally in the lower part of the abdomen. She had two attacks of peritonitis, but was frequently confined to bed for a day or so. Occasionally she had slight chill and fever. A few months ago she noticed a swelling in the left side of the lower part of the abdomen. She consulted Dr. G. Gross, who made a diagnosis of pyosalpinx and advised that an operation be performed. In a subsequent examination by Dr. G. Gross and myself, Dr. Gross stated that the mass was only about one-half its former size.

Examination showed the uterus in normal position and moderately movable. A mass, tender to the touch, occupied the left side of the pelvis and extended to the side of the uterus. The right tube and ovary could not be thoroughly examined. Some thickening was felt, and slight pain on pressure.

On November 11, 1896, with the valuable assistance of Dr. G. Gross and Dr. O. Parrone, I made operation under chloroform, which was administered by the drop method.

Examination under chloroform showed the uterus in normal position; on the left side was a large adherent mass, extending to the uterine cornua; the right ovary was enlarged to the size of a mandarin orange, and moderately adherent.

Diagnosis: Endometritis, left pyosalpinx with adhesions, right ovary enlarged and moderately adherent.

The patient was placed in the lithotomy position; the cervix was dilated and the uterus curetted. Carbolic acid and tincture of iodine, one in four, were applied to the endometrium. The cervix was again dilated and the uterus irrigated with boiled water. She was then placed on the back, with legs extended, and an incision about three inches long was made above the pubes, dividing slightly to one side of the median line the skin, the subcutaneous tissues, the fascia, the rectus, and the peritoneum. On the introduction of two fingers, the omentum and intestines were found adherent to the appendages and the fundus. On account of the extent of the adhesions and the size of the masses, it was found necessary to enlarge the incision slightly. Three and three-fourths inches was the length of the entire incision. The fundus uteri could not be felt at first, so the adhesions on the left side were separated with the fingers till the mass on this side could be partially felt. Carefully working toward the fundus, separating the adherent omentum and intestines, after a while we exposed the fundus. The left mass was enucleated, beginning at its outer extremity. During the separation of adhesions it ruptured, and about one-half pint of creamy chocolate-colored fluid escaped. Pitcherful after pitcherful of hot water was poured in, till the fluid came away clear. The blunt dissection, aided at times by cuts from the scalpel, was carried as close as possible to the adherent mass (a tubo-ovarian abscess). The enucleation was continued as far inward as the cornua of the uterus, from which the mass was separated by dissection flush with the uterus. The pedicle was not tied or clamped, but was removed by enucleation without ligature, forceps, or cautery. There was no bleeding vessel. The adhesions behind the uterus were separated, except deep down in the pelvis. The right ovary was next sought for, and was found adherent; the tube was apparently normal. The ovary—of the size of a mandarin orange—was separated from the adhesions and the surroundings, and with the tube was enucleated by blunt dissection, aided at times by cuts with the scalpel. When the uterine end of the tube was reached, the serosa of the tube, about one-fourth of an inch from the uterine cornu, was divided in a circle and dissected back to the uterus. The tube was then cut off at the tubo-uterine junction, and the cut edges of serosa which had been dissected back were united with a continuous catgut suture. The oozing from the adhesions was arrested by irrigation with hot water and sponge pressure. A couple of tears on the uterine fundus were closed with continuous catgut sutures. Two narrow gauze wicks were carried down to the cul-de-sac, and the ends brought out through the lower angle of the wound. The omentum was drawn down and spread over the intestine, and then the cut edges of the peritoneum were united with a continuous fine chromicized catgut suture. The divided rectus and fascia were united with a continuous chromicized tendon suture, and for the fine approximation of the edges of the fascia a layer of fine chromicized catgut was also introduced. The skin edges were sutured with fine silk. Only sufficient room was left at the lower angle for the passage of the gauze wicks. The uterus was not removed, as it was in good position and had been curetted.

Dressing and after-treatment: Moist bichloride of mercury gauze, held in place by long strips of adhesive plaster, cotton, and binder. The moist dressings were changed as often as they were saturated—about every three hours for the first few dressings, every four hours on the first day, every six hours on the second,

and twice on the third. The gauze wicks were shortened on the third day. The remaining portions of the wicks, except a short piece, were removed on the fourth; and on the morning of the fifth the piece was withdrawn, when a narrow strip of moist gauze was introduced and the edges of the small wound were allowed to fall together. Recovery was satisfactory, the wound healed by primary union, and the silk stitches were removed on the seventh day.

From a study of this case and others I have operated upon successfully,[1] I draw the following conclusions:

1. That even when the appendages, etc., are the seat of extensive adhesions, a pyosalpinx, a tubo-ovarian abscess, and ovarian, uterine, or other cyst, tumor, etc., can be removed by enucleation.

2. That enucleation is the simplest and safest method of removing ovarian, uterine, or other cysts, tumors, etc. There is no danger of hemorrhage. If a vessel is severed, it can be caught at once and ligated.

3. That an ovarian, uterine, or other pedicle should not be transfixed and tied with mass ligatures or tied off in sections, but should be cut across and only the individual vessels ligated. This does away with mass, non-absorbable, and dead ligatures, the cautery, sloughing, and painful stumps, pelvic exudates, and wandering ligatures.

4. That with enucleation, the danger of injuring the surrounding structures is slight, recovery is rapid, and the danger of sepsis is reduced to the minimum.

5. That when a Fallopian tube is removed, it should be removed completely—no stump should be left. When the serosa of the tube at the tubo-uterine junction is not destroyed, it should be divided in a circle and dissected back to the uterus, and after the tube is removed the cut edges united with a continuous absorbable suture.

6. That after removing an appendage, etc., the cut edges of the broad ligament should be united with a continuous suture.

7. That even when both appendages are removed, a uterus that is in good position and not irreparably damaged should not be extirpated.

8. That it must be remembered that at times enucleation with ligation of vessels only is very difficult—*e.g.*, when the pedicles are short and deeply located in the pelvis, and thus cannot be easily controlled; when the broad ligaments retract quickly; when the surgeon cannot or does not wish to keep close to the cyst or tumor, etc.; when the broad ligaments are thickened and very vascular; and when the uterus is fixed by peri-uterine or other adhesions.

Under these circumstances, the surgeon should, in treating the pedicle, first separate adhesions, then enucleate the mass, so as to expose the pedicle, which is clamped transversely, as many forceps as necessary being applied. The operator should then cut off the pedicle between the tumor and the clamps; make moderate traction on the latter, which are used as a lever and tractor, to bring the severed pedicle well into view, so as to inspect the stump for mouths of vessels, which are ligated separately. When the clamps are removed, first apply small forceps at the upper and lower angles of the pedicle to control it; and, if it has a serous coat, bring the cut edges of the latter together over the stump with a continuous suture, to leave no raw surface exposed to form adhesions. The clamps are an addition to the enucleation method, and when applied to the pedicles act temporarily as a prophylactic against hemorrhage while the individual vessels are ligated, at the same time the forceps being used as a lever and tractor. The pedicle is easily controlled and manipulated, the stumps inspected, and the vessels located and ligated.

ATRESIA OF THE VAGINA.

By R. J. Wilson, M.D.,

Toronto, Canada.

Mary S——, aged fifteen years. Family history good; had measles in infancy; otherwise enjoyed good health until thirteen years old. Since then she has complained of headache, general weakness, and constipation: has lost color, and from a plump, rosy child she has become a pale, listless girl, suffering from headache almost constantly, which for days at a time confined her to bed. For this condition various remedies have been prescribed without any improvement. She has never menstruated, and her parents were assured that just so soon as this evidence of womanhood appeared she would be well. She has monthly for the past two years all the symptoms of menstruation, such as pains in the back and down the thighs, and headache, but no flow. The pains have increased much in severity of late; she is losing strength, and is now compelled to keep to her room for a week each month. The bowels move only when encouraged, and she complains of the loss of power to defecate. There is no pain in urinating, but the flow is slow. I saw the patient for the first time on October 23, 1896, and insisted upon a thorough examination. On explaining to the mother that perhaps there was some mechanical reason for the non-appearance of the flux, she consented. On examination the breasts were found well developed, the pubic region was covered by an abundance of dark hair, the urethra and rectum were normal.

The external genitals were well formed, though separated by a very tense bulging mass apparently containing fluid.

Examination revealed the fact that the entrance of the vagina was completely sealed by a dense fibrous band attached to the vaginal walls about one inch above the vulvo-vaginal orifice. On examination per rectum, the true pelvis was found completely filled by a cystic mass, the rectal space being obliterated.

On examining the abdomen a tumor was found in the middle line extending from the symphysis pubis to one and one-half inches above the umbilicus, and occupying the whole of the hypogastric, umbilical, and the lower one and one-half inches of the epigastric regions, almost filling the flanks on each side.

The tumor resembled in size and shape a pregnant uterus at the end of the sixth month; it was very tense and contained fluid; pressure upon the tumor increased the tension of the cyst-like mass separating the labia. The history and the conditions mentioned made the diagnosis of atresia of the vagina quite clear.

Immediate operation was advised and agreed upon. The patient was prepared. On the following morning, assisted by Dr. W. B. Thistle, I operated. An anæsthetic was administered, when very careful search was again made to find if possible an opening in the membrane; none was found. A central transverse incision was then made in the occluding band, through which escaped about five pints of dark chocolate-colored fluid: after the escape of the fluid the operation was completed by rapidly dissecting away the membrane with scissors. There was very little hemorrhage. The central portion of the band was about one-eighth inch in thickness, while the attached margins were fully three-eighths inch in thickness. The vagina above the band was enormously elongated and dilated, and it was with difficulty that the cervix was reached; the os and cervix were dilated and readily admitted two fingers, while the cavity of the uterus was quite patent.

After a thorough cleansing of the parts a strip of iodoform gauze was introduced into the cavity of the uterus, and the vagina was packed with strips of the

same. This was changed daily for three days, after which a simple douche was ordered.

On becoming conscious, the patient complained of feeling faint, and eight hours after the operation the temperature was 100 F.; pulse, 118. At no other period in the subsequent history did the temperature exceed 99 F. The recovery was uninterrupted. A mixture of ergot, strychnine, and iron was given. The uterus occupied the true pelvis seventy-six hours after operation. On examination it and the appendages were found normal in all respects.

20 Bloor Street, W., November 28, 1896.

Progress of Medical Science.

The Treatment of Gonorrhœa with Methylene Blue.—Moore (*British Medical Journal*, January 16, 1897, p. 140) reports in detail two cases of gonorrhœa and refers to seven others treated by the administration of three grains of methylene blue, together with fifteen or twenty grains of potassium citrate, thrice daily, with the result of cutting short the acute stage and alleviating the patient's sufferings. In the later stage an injection of three grains of alum in an ounce of hot water was also employed thrice daily.

The Pathology of the Diarrhœal Disorders of Childhood.—Baginsky (*Berliner klinische Wochenschrift*, January 11, 1897, p. 22) expresses himself of the opinion that the diarrhœal disorders of childhood occurring in conjunction with elevated summer temperature, appear first as functional (chemic) disturbances and subsequently as profound organic lesions of the intestinal wall. For the development of these conditions the ordinary saprophytic bacteria of the intestinal contents and not specific bacteria must be held responsible. The active organisms cause injury to the intestinal walls through the putrefactive processes of toxic character or through products usually non-toxic in character (ammonia and its derivatives), inasmuch as they act as inflammatory irritants; or they cause degeneration of the vegetative and the most important excretory organs (liver, kidneys, etc.) through the blood stream and the lymph stream. As a result of the interference with nutrition and the diminution in the resistance of the tissues thus brought about, the organism is exposed to the invasion of pathogenic bacteria of all kinds (staphylococci, streptococci, pneumococci, oidium albicans, etc.). There also results a predisposition to disease, as manifested by numerous complications.

Motor Aphasia in a Child during the Early Stage of an Acute Exanthem.—Brasch (*Berliner klinische Wochenschrift*, January 11, 1897, p. 30) has reported the case of a girl, aged three years and ten months, without hereditary predisposition or previous abnormality, who became peevish, and then delirious and finally unconscious, with incontinence of bladder and bowels. In the mean time a scarlatinal eruption made its appearance, extending from the feet over the entire body, and the temperature rose to 105.3° F. There was, however, neither angina nor strawberry tongue and no vomiting. The urine was free and contained no albumin and the bowels were constipated. On the third day a similar eruption appeared upon a younger sister, though the attendant symptoms were milder in intensity and extent. In the course of a week the sensorial disturbances in the first child gradually subsided, but the power of speech was lost, although the child appeared to understand all that was said. The ears were normal. The heart presented no lesion. The pupils were moderately large and reactive. The face was symmetric and the muscles of both sides acted equally. Branny desquamation took place from the cutaneous surface, followed by a varicellous eruption upon the face. The knee jerks were preserved. The gait was oscillating, though not ataxic. Speech returned gradually and steadily and control of the sphincters was regained. Recovery was apparently perfect at the end of five or six weeks, although speech remained a little slow and monotonous. The case is viewed as one of atypical scarlatina, with aphasia of toxic origin.

Acute Generalized Miliary Tuberculosis, Involving also the Skin.—Although acute miliary tuberculosis cannot be regarded as especially uncommon, involvement of the skin in the general process is exceedingly rare. A unique case of this character has recently been reported by Leichtenstern (*Münchener medicinische Wochenschrift*, January 5, 1897, p. 1). A boy, five years old, previously healthy and with a good family history, had an attack of measles, from which he failed to recover perfectly, presenting marked febrile symptoms of remittent type. The pulmonary physical signs were insignificant and consisted in slight evidences of bronchitis in both lower lobes. The skin, which was frequently examined for rose-spots, was at this time quite normal. The spleen was strikingly enlarged. The bronchial physical signs increased in intensity and extent, and to them became added evidences of effusion into the left pleura, together with dyspnœa and cyanosis. The pulse had been rapid from the beginning (120 to 140). The temperature later assumed a more intermittent character and profound sweats occurred, with loss of strength and flesh. There was only slight cough and this was unattended with expectoration. In the second week of observation, *i.e.*, six weeks after the attack of measles, a number of small, bright-red, hard, conical nodules, with sharply circumscribed bases, were observed on the face. In the further progress of the case, similar nodules appeared upon many other parts of the body. The larger number of these underwent retrograde changes and disappeared in the course of from a week to two weeks with desquamation. At the summit of other nodules vesicles formed, which speedily dried and disappeared. Upon still others appeared pustules, which also underwent involution. As old nodules disappeared, new ones appeared in remote situations. At no time, however, was any considerable number present; nor was there any evidence of a tendency to spread locally, the nodules always remaining discrete. The cervical, axillary, and inguinal lymphatic glands became enlarged. The conclusion was reached that the cutaneous lesion was either tuberculous or tuberculo-toxic, and instructions were given to excise a nodule for histologic study, but this was for some reason not done. Examination of the contents of a pustule disclosed the presence only of streptococci. In the fourth week miliary nodules appeared upon the mucous membrane of the lips, breaking down and leaving superficial ulceration. A similar series of changes was noted also upon the tongue. At the end of the sixth week the child died, amid typical symptoms of tuberculous meningitis, which was confirmed by the post-mortem examination. In addition, the lungs and the pleura on both sides were found to be the seat of miliary tuberculosis, the lower part of the left lung being converted into a homogeneous cheesy mass. Several bronchial lymphatic glands also were caseous. The follicles of the mucosa of the small intestine were distinctly swollen. The mesenteric and retroperitoneal glands were partly cheesy. Liver, spleen, and kidneys were the seat of tubercles. Examination of two of the cutaneous nodules disclosed the histologic structure of a tubercle in the papillary layer of the skin, with the presence of tubercle bacilli.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHERS

WM. WOOD & CO., 43, 45, & 47 East Tenth Street.

New York, February 13, 1897.

THE PLAGUE.

THE disease now scourging Bombay is probably the same as that which occurred in various epidemics in the principal centres of population in Europe in the middle ages, although it is possible that several different diseases were formerly called by this name when encountered in epidemic form. The great plague in London seems certainly to have been a visitation of this disease, for the description of Defoe, making allowances for the exaggeration of a layman and a writer who wished to construct a good story, is a fairly accurate account of the most striking symptoms of the plague as it has been observed in China and India during the past three years. The last great epidemic occurrence of the plague in Europe was at Marseilles and in other parts of France in 1720, but the disease has visited Europe several times since then, the last time in the province of Astrakhan in Russia in 1878-79. So little has been heard of it since then that to most physicians it has existed merely as a name in medical history. It has never died out, however, but has floated about in Asia, now rising to the dignity of an actual epidemic in one place, again being heard of as occurring sporadically in some distant region seldom visited by Europeans. The present recrudescence was first heard of in Canton in February, 1894, although the disease was known to be prevailing in southern China for at least fifteen years before that time, usually in sporadic form but occasionally in local epidemics of extreme malignancy. From Canton the plague passed to Hong-Kong, or perhaps came there from some other direction, becoming epidemic in May of the same year. The following year it was heard of again in the same cities, and in 1896 invaded Bombay and other places on the west coast of India.

There was little doubt that the disease was of bacillary origin, but the demonstration of this was lacking until Kitasato discovered a micro-organism in the blood and enlarged lymphatic glands. There seems to be some uncertainty concerning the morphology of this micro-organism. Kitasato found a bacillus in the blood which resembled the microbe of chicken cholera, apparently surrounded by a capsule, and staining chiefly at the extremities. Aoyama, Kitasato's associate, has suggested that this is really a diplococcus, and not a bacillus. The bacillus found in the glands had rounded extremities, no capsule, and stained quite uniformly. Lowson, who was also working in Hong-Kong at the same time, thought the difference in these two forms was an artificial one, the organism when stained lightly appearing as a diplococcus, but when more deeply stained being seen to be a bacillus. Yersin in Amoy found a bacillus with rounded ends staining well, but more deeply at the extremities than in the centre. Inoculation experiments by all these different observers have shown the micro-organism to be pathogenic, the inoculated animals succumbing with the symptoms of true plague.

There is considerable difference of opinion as to the method of spread of the disease. Europeans and half-breeds are far less frequently attacked than pure-blooded natives, and then apparently only when there has been prolonged actual contact with the sick, as was the case with two nursing sisters who carried sick children in their arms; or when Europeans have remained some time in infected localities, as happened in Hong-Kong when a number of British soldiers were employed in cleaning out the indescribably filthy houses inhabited by Chinese in the infected quarters of the city. Yet even natives, when clean of person and living in clean well-ventilated apartments, do not seem to be in much danger. Dr. Cantlie, in a recent address before the Epidemiological Society of London, says that none of the Chinese students in the College of Medicine at Hong-Kong was attacked, although they were on duty, night and day by turns, for six weeks in the plague hospital, and were during that time in constant contact with the sick. None of the European physicians, fifteen in number, in attendance upon the plague patients, acquired the disease. Dr. Aoyama had the plague and recovered, but it is not at all improbable that he became accidentally inoculated while prosecuting his pathological and bacteriological studies. Several of the lower animals suffer from the disease, rats especially. Indeed, the natives in plague districts often predict an invasion of the disease by observing an unusual mortality among rats. In Bombay it is believed that the rats dying of the plague are eaten by ants and that the latter carry the bacilli to the food or water. The plague has often prevailed in places where there are few or no ants, but other insects, house flies for example, might readily spread the virus. However the infection is carried, it seems to be very certain that persons, whether foreign born or natives, who are clean and live in well-kept airy apartments and upon nourishing and well-prepared food, are practically immune. In other words, the plague is pre-eminently a filth disease, and one that could gain no foothold in a community where modern sanitary rules govern. It is not a disease which New York, for example, has any reason to fear.

The disease usually begins abruptly with a chill, or sometimes a glandular swelling is the first sign of infection. Fever sets in early, the temperature rapidly rising to 104° F. or higher. The pulse is weak, sometimes dicrotic, and ranges from 100 to 120. There are the usual accompaniments of adynamic infectious diseases, such as headache, nausea, vomiting, and de-

lirium. The urine is albuminous. The glands are always enlarged, and sometimes their involvement goes on to suppuration. This suppuration seems, however, not to be characteristic of the disease, but rather to be a complication due to the accidental presence of pyogenic bacteria. Aoyama found, indeed, that the occurrence of suppuration in an enlarged lymphatic gland was seemingly destructive of the specific plague bacillus. The glands involved most frequently are those of the axilla, neck, and groin, though any of the lymph nodes may be affected. The enlargement frequently occurs in several groups of glands in succession. In rare cases no glandular involvement can be detected during life.

The mortality of the disease is very high, sometimes being as great as ninety-five per cent. of those attacked. In the present Chinese and Indian epidemics the deaths among Europeans were from eighteen to twenty per cent. of those attacked. Death usually occurs in from two to eight days. The incubation period has not been definitely determined, but is probably from three to seven days, although there are cases on record which would appear to prove that this period may exceptionally be extended to ten days or two weeks.

The treatment usually recommended consists wholly in supporting-measures, but its efficacy is very doubtful. Yersin claims to have elaborated an antitoxic serum of great efficacy, and it is said that the government has decided to make use of this in Bombay, Yersin being now on his way to India. It is said, however, that it requires six months to prepare the serum; so, unless he has been laying up a supply during the past year there would not appear to be much relief in sight from this source in Bombay. Yersin first inoculates rats and then horses from them. He tried the serum in 1895, in a French mission station in Amoy, with, it is affirmed, remarkable success, many who were already comatose when the injections were made having been cured.

There is a prophylactic possibility in the existence of an affection resembling the bubonic plague, but without its malignancy. This disease, pestis minor, which prevails at the present time in Calcutta, is of epidemic character, is characterized by polyadenitis, and shows in the blood and glands a bacillus very like Kitasato's, but it is attended by a low death rate. It is possible that this may be an attenuated form of the plague, related to it perhaps as cow-pox is to smallpox. If so, it may be that inoculation with pestis minor will be found to confer immunity against the bubonic plague. This, of course, is pure speculation, for we do not as yet know enough of the two diseases bacteriologically to say how nearly related they are, if they are related at all, but it is an interesting speculation.

PREMATURE BURIAL.

During the past ten days the lay press has devoted much space to the question of the possibility of the living being buried and the reliability of the usual tests applied to determine that death has surely taken place. The majority of instances one finds recorded of a return to life and "a struggle in the grave" are based upon faulty deductions. The body being found in contracted and distorted positions, with hands clenched, hair torn out, blood stains present, etc., is to be explained by natural conditions. In an editorial on December 26th last, we called attention to the shameful manner in which the supposed dead are hurried away by undertakers to be frozen, and ventured the opinion that physicians are not blameless in the matter. In most instances there seems no objection to giving the subject the benefit of the doubt, and, at least for some hours, refraining from putting obstacles in the way of a renewal of vital function. During the cholera in New York many years ago, there were instances of auto-resuscitation after supposed death, and, if we mistake not, this disease is peculiarly likely to result in a state of pseudo-death. The question comes up with periodical regularity, and each time it is discussed a sufficient number of authentic instances of "coming to life again" before burial are recorded to make it quite easy to believe that more instances of burial while the supposedly dead are still alive do in reality occur than physicians as a rule have been willing to admit. When, however, Mr. Sextus says he is almost of the belief that in nearly five per cent. of human burials there is still life in the subject, we must refrain from according to his observations that credit which might otherwise be due them.

QUOTATIONS FROM THE MEDICAL RECORD.

We notice that a letter has been sent to the medical journals of this country and of Canada, which by the inference it carries is calculated very naturally to place the Medical Record and its publishers in a false position.

Both editor and publishers of the Medical Record realize most fully that the best interests of the medical profession are equally theirs, and they would be the last to countenance any action which might interfere in the slightest degree with the fullest and freest dissemination of knowledge. The Medical Record has always allowed the free use of the original matter contributed to it for all reputable purposes, provided that due credit is always given to the original source of publication. There is no reason to believe that its policy in this respect will ever be changed.

The refusal to allow the editor of a certain publication to make extracts from the Medical Record and *The American Journal of Obstetrics* was based upon sound business reasons, and applies only to that particular case.

The letter above referred to, while plausible on its face, is misleading in its intent, inasmuch as it implies that our course in this one instance might be considered as characteristic of our general policy, than which nothing is more untrue.

It is to be regretted that the matter should have been obtruded upon the notice of the medical profession, and the suspicion naturally occurs that the principal object in view may have been a widespread

advertisement of a forthcoming book which the writer has contracted to compile.

We do not intend to enter into any controversy, but we believe that this plain statement of our policy as regards the MEDICAL RECORD will assure the medical profession that any ideas such as this letter was calculated to suggest are absolutely without foundation.

ONE THING AT A TIME.

IT is sometimes said, more expressively than elegantly, of a man who has undertaken a task beyond his power of accomplishment that he has bitten off more than he can chew. The board of health of this city seems to be in a predicament of that sort just at present. Some months ago notices were conspicuously posted in all the elevated and surface cars, setting forth that spitting was a nuisance, a disgusting practice, and a menace to public health. After this statement of fact follows a paragraph to the effect that spitting is forbidden in the cars, and that the rule will be enforced. The notices are still displayed in some of the cars, perhaps in all, but they might as well be in Calcutta as far as they concern spitters in New York. The conductors, who are supposed to enforce the law, are in many cases the worst offenders against it. We have known of an instance in which complaint was made against a man who was sprinkling the floor of a car with saliva; the conductor, being asked to make him desist or leave the car, as soon as he could clear his own mouth of the tobacco juice which filled it, laughed and said that the notice meant nothing, and it was none of his business what the passenger did as long as he was making no disturbance.

The board of health of this city has done some excellent work and has won the respect of the medical profession as well as of other citizens, but it will make itself an object of ridicule if it promulgates laws which it cannot enforce. It has recently proposed to declare tuberculosis a contagious disease and to compel its notification. We do not know what it proposes to do with the consumptive after it catches him—perhaps to send him a notice that spitting is a disgusting practice and dangerous to public health. We cannot but think that it would be wiser to see that one rule is properly executed before another is put forth. Perhaps the prestige of having put an end to spitting in public places would carry the board to the point of being able to enforce the notification by physicians of cases of tuberculosis occurring among their *clientèle*. But for the present one dead-letter health law is enough.

To Prevent Premature Burial.—The cable reports that some one in Vienna has discovered a new kind of Roentgen rays, which will infallibly determine in a subject whether death or catalepsy has intervened. An investigation of this claim is recommended to those gentlemen who are alarming us with the assertion that premature burial is of frequent occurrence.

News of the Week.

The Health of the Tsar.—Some time ago it was reported that a Berlin surgeon had been called to St. Petersburg to trephine the Tsar's cranium, but a few days later the report was emphatically denied by the surgeon himself. Now another report comes from Berlin to the effect that the young Nicholas is an epileptic, and that his attacks are recurring with increasing frequency. His physicians, it is said, have prescribed a strict regimen, cutting off his tobacco. It is impossible to learn what truth there is in this rumor, but we trust there is none.

Strengthening the Quarantine Station.—Governor Black recently signed the bill, introduced by Assemblyman Nixon at the request of Health Officer Doty of the port of New York, appropriating $5,000 for the completion of the disinfection apparatus at the quarantine station of the port of New York, to prevent the introduction of infectious and contagious diseases. The measure is a precaution taken against the possibility of the introduction into this country of the bubonic plague.

A Rinderpest Serum.—Koch has completed his studies of the rinderpest in South Africa, and has sent word that he is about to return to Berlin with a newly discovered serum which will lessen the force of the disease. In the mean time, he is unable to say whether or not he will be able to prevent animals from being infected with the disease. He has demonstrated that sheep and horned cattle are the most liable of all animals to contract the disease, and that dogs, monkeys, and rodents enjoy complete immunity from it.

The Plague.—Up to February 4th, according to the official returns, there had been in Bombay 5,098 cases of the plague, with 3,841 deaths. Several of the European governments are sending commissions to India to study the disease. It was announced that Koch was to head the one sent by Germany, but a dispatch from Berlin says that he has telegraphed from South Africa his refusal to go to Bombay. Yersin is now on his way there, having been invited by the government to make a trial of his antiplague serum which was found so effectual in Amoy last year. A sanitary conference has been called to meet in Venice on February 12th. It is announced that the British delegates will refuse to sanction the adoption of stringent quarantine restrictions, urging rather upon the delegates from southern Europe the prophylactic virtues of cleanliness, both personal and municipal. It is announced by the governor of the Transcaspian territories that the bubonic plague has appeared at Candahar, Afghanistan. A force of Cossacks has been sent to the Amu Darya River to prevent, if possible, the introduction of the disease into Russian territory.

The Polyclinic Hospital.—The trustees of the New York Polyclinic Medical School and Hospital have decided to rebuild on the site of their former building, which was burned some weeks ago. The work will be begun immediately.

The Successor of DuBois-Reymond in the chair of physiology at the Berlin University will probably be either Professor Munk, of Berlin, or Professor Kühne, of Heidelberg.

Obituary Notes.—Dr. Charles W. Cooper, of Northampton, Mass., was lost at sea from the steamship *Columbia*, which arrived here from Genoa on February 8th. Dr. Cooper was born in Maine in 1851. He was graduated from Amherst College in 1873 and from the Harvard Medical School in 1876. For a time he was surgeon on a steamship on the Pacific, and then settled in Northampton.—Dr. Charles A. Stark, of Marshfield, Mass., died there on January 22d, aged thirty-five years. He was a graduate of the Dartmouth Medical School. He was for a time connected with the staff of the New Hampshire Insane Asylum, and then went South, practising his profession in Louisiana. In 1889 he returned North and in the following year established himself at Marshfield. —Dr. Ramon De Mazarrado died at Philadelphia on January 3d at the age of sixty-two years. He was a native of Cienfuegos and a graduate of the medical department of the University of Pennsylvania. He continued his medical studies abroad, and then returned to Cuba.—Dr. William A. Carey died at Philadelphia on January 29th at the age of thirty-five years.—Dr. Andrew Wittkamp died at Philadelphia on February 2d, at the age of forty-one years, as a result of cerebral hemorrhage. He came from Germany as an infant and was graduated from Jefferson Medical College in 1876.

Philadelphia Neurological Society.—At a stated meeting of the Philadelphia Neurological Society on January 25, 1897, Dr. Lewellys F. Barker, associate professor of anatomy in the Johns Hospital University, read a paper entitled "Flechsig's Association Centres in the Cerebral Cortex."

Orrhotherapy in Puerperal Septicæmia. — The Kieff (Russia) Society of Gynecology and Obstetrics has issued a circular, requesting all members of the profession who have tried any experiments in the use of antitoxin in septic diseases following delivery to communicate the results to the president, Prof. G. E. Kehn, Bolshaya Vladimirskaya, Kieff, Russia. The material thus brought together will be carefully examined and submitted for discussion to the section of obstetrics at the forthcoming international medical congress.

Rontography.—A writer in *The Lancet* suggests that the pictures obtained by means of the Roentgen rays be called, as a tribute to the discoverer, rontographs, and the process rontography.

Against Illegal Practitioners.—Since April, 1895, when the law providing for the criminal prosecution of quacks was restored, the New York County Medical Society has caused the arrest of eighty-three persons for practising illegally, and it has obtained convictions in fifty-one cases. These persons have paid $3,690 in fines, and a number of them have been sent to jail besides. The legal department of the society has a large number of cases pending.

Dr. George W. Brush, of Brooklyn, is, by direction of the President, to receive a medal of honor for distinguished gallantry in action on the Ashepoo River, South Carolina, on May 24, 1864. Dr. Brush, then a captain of infantry, volunteered to command a boat crew which went to the rescue of a large number of Union soldiers on board the stranded steamer *Boston*, and succeeded in conveying them to the shore, being exposed during the entire time to a heavy fire from a Confederate battery.

The Night Medical Service in Paris.—Some time ago a night medical service was established in Paris, the fee being placed at 10 francs. It has grown to such an extent, however, that the police authorities are endeavoring to reduce the expense, and with this object propose to give the physicians employed in the service an annual salary of 600 francs ($120). This would be an equivalent of about sixty cents a visit in the poorer districts, where the night calls are the most numerous, and the physicians concerned refuse to serve for so small a compensation. The prefect of police pretends not to be alarmed, for he thinks there are enough needy practitioners who will be glad to take the vacant places and do the work for $10 a month.

Small-Pox in Cuba.—There are over two thousand cases of small-pox in Havana, and the disease is proportionately prevalent in other cities of Cuba. In Guanajay, in Pinar del Rio, there are reported to be four hundred and sixty-seven cases in a population of less than ten thousand. Yellow fever is less virulent for the time being, but in two months the hot weather will set in, and then the disease will undoubtedly become even more deadly than during the last rainy season.

A Surgical Doorkeeper.—As an illustration of the overcrowded state of the medical profession, says the *Medical Times* (London), an evening newspaper states that at the present time the doorkeeper at one of our London workhouses is a pauper who holds the diploma of fellow of the Royal College of Surgeons of England. It is stated that at one time the "fellow" in question had an excellent practice, kept horses and carriages, and was chief medical officer of a county asylum. Now he wears workhouse fustian, with brass buttons, and is glad to touch his hat to all comers. Our contemporary says that competition alone could not have reduced the man to such straits, for, it optimistically thinks, although the profession is much overcrowded, every well-educated and well-conducted doctor should not experience much difficulty in earning sufficient to live respectably.

The American Medical Association.—It is announced by the committee of arrangements for the fiftieth annual meeting of this society that, in addition to the regular order of exercises during the meeting, there will be, for a week preceding and a week succeeding the meeting, special courses and clinics given in the various teaching institutions of Philadelphia, without cost to visiting physicians. Information concerning these may be obtained from Dr. Edward Martin, 415 South Fifteenth Street, Philadelphia, chairman of the committee on hospital courses.

A Prophetic Utterance.—The London *Daily News* relates the following story in a notice concerning the honor recently conferred on Sir Joseph Lister: While going round his wards in the Glasgow Royal Infirmary one day, Sir Joseph, then plain Mr. Lister, came to the bedside of a patient whose arm had been severely crushed without the skin having received any injury. Turning to the assembled students, he said, "Gentlemen, I have frequently noticed that when severe injuries are received without the skin being broken, the cases nearly always recover. On the other hand, trouble is always apt to follow, even in trivial injuries, when a wound in the skin is present. How is this? I cannot help thinking that the man who is able to explain this problem will be one who will gain for himself undying fame." The problem was solved by the speaker himself, and the fame has been gained.

A One-Man Medical Faculty.—Dr. Dunglison writes in the *College and Clinical Record* that the late Prof. Robley Dunglison, of Jefferson Medical College, when invited by the representative of Thomas Jefferson, then rector of the University of Virginia, to leave England to assume the duties of a professorship—or rather a combination of professorships—in that school, entered into a contract: "To teach to the best of his ability and with due diligence, anatomy, surgery, the history of the progress and theories of medicine, physiology, materia medica, and pharmacy." At the time he was invited to take upon himself this task he was but twenty-six years of age.

Dr. Giuseppe Sanarelli, the alleged discoverer of the yellow-fever bacillus and of a curative antitoxin of the disease, is a graduate of the University of Siena in 1889. He early turned his attention to the study of water-borne diseases. He studied for a time at the Pasteur Institute in Paris and on his return to Italy was appointed professor of hygiene at the University of Siena. Upon the establishment of the Institute of Experimental Hygiene in Montevideo he was chosen as director at a salary of $5,000. While in Brazil he contracted yellow fever, and after his recovery declared war on the disease and set about the discovery of its cause. We earnestly hope he has been successful, as announced, but we cannot forget that Freire and others have thought that they had discovered the secret and have been shown to be mistaken.

College of Physicians of Philadelphia.—A stated meeting of the College of Physicians of Philadelphia was held on Feburary 3d. Dr. Thomas G. Morton read an appreciative memoir of the late Dr. William Hunt, based upon a personal acquaintanceship of some forty years. A discussion upon "The Relations of Nervous Disorders in Women to Pelvic Disease," was participated in by Drs. B. C. Hirst, E. E. Montgomery, G. E. Shoemaker, C. P. Noble, S. Weir Mitchell, C. K. Mills, Wharton Sinkler, F. X. Dercum, J. Hendrie Lloyd, James Tyson, A. V. Meigs, J. M. Anders, L. W. Steinbach, and S. Solis-Cohen. The consensus of opinion appeared to be that pelvic disease alone is not competent to cause nervous disorders, and that the removal of healthy or slightly diseased pelvic organs for the cure or alleviation of such disorders is not justifiable, although it was agreed that pelvic disease in nervous women should receive precisely the same therapeutic consideration as in women free from nervous disorder. Dr. J. K. Mitchell was elected a councillor and three new fellows were elected.

The New London County (Conn.) Medical Society held its annual meeting at the residence of Dr. J. G. Stanton, on January 14th. Dr. E. P. Douglass read a paper embodying the report of a number of surgical cases seen by him. The election of officers resulted in the choice of the following: Dr. F. W. Dart, Niantic, *President;* Dr. J. R. Crofton, *Vice-President:* Dr. H. H. Meyer, *Secretary:* Dr. Hughes, Groton, *Librarian and Curator.*

Plenty of Doctors in South Africa.—It is said that every small village in Cape Colony and Natal is well supplied with medical men (mostly of Scotch or German nationality), and in the larger towns the supply largely exceeds the demand.

A Training School for Colored Nurses is about to be established in Charleston, S. C. One was recently founded in New Orleans.

Plural Births in Massachusetts.—During 1896 there were one thousand four hundred and seventy-two twins and twenty-seven triplets recorded in Massachusetts.

Antivaccinators.—Pennsylvania shares in the distinction of possessing a so-called Anti-compulsory Vaccination League, the president of which and ten vice-presidents appear to be homœopathic physicians. At a recent meeting a petition to the legislature was adopted, asking that the compulsory-vaccination law be repealed.

Vital Statistics of Philadelphia.—For the week ending January 30th there were reported to the Philadelphia board of health 556 deaths—108 more than during the preceding week and 57 more than during the corresponding week of the previous year. Of the whole number 150 were of children under the age of five years. The individual causes of the largest number of deaths were as follows: Pneumonia, 107; pulmonary tuberculosis, 72; heart disease, 35; diphtheria, 34; old age, 23; apoplexy, 22. During the week there were reported also 106 cases of diphtheria, 46 of scarlet fever, and 27 of typhoid fever.

To Discourage Vivisection.—The latest scheme for discouraging vivisection, as promulgated by the American Antivivisection Society, of which a graduate in medicine—we blush to record it—figures as the president, is to "search out, under capable medical direction, all varieties of cruel work by vivisectors, and, giving it the widest publicity, mention the name and address of the perpetrator in every case." We venture to state the list will be a small one, as so-called vivisectors are moved by no less lofty and delicate sentiments than the self-assuming antivivisectors.

A Botanical Doctor Called to Account.—A colored man of Philadelphia, known as a botanical doctor, has just been convicted of involuntary manslaughter and sentenced to imprisonment for a year and the payment of a fine of $500. It appears that the "doctor" had administered to a sick man suffering from abdominal pain a decoction of his own preparation. Death resulting, appendicitis was found to exist, the fatal result of which might have been averted by appropriate operation.

The German Congress for Internal Medicine will hold its fifteenth annual session in Berlin on June 9 to 12, 1897. The meetings will be held in the Architektenhaus, in the Wilhelmstrasse, under the presidency of Professor von Leyden. The subjects announced for discussion are the "Treatment of Chronic Articular Rheumatism," opened by Bäumler and Ott; "Epilepsy," opened by Unverricht; and "Exophthalmic Goitre," opened by Eulenburg.

New Jersey Board of Medical Examiners.—The sixth annual report of this board states that during the year 1896 seventy-five candidates made application for examination for license to practise medicine and surgery in that State, in accordance with the provisions of the law. Two candidates subsequently withdrew before completing the examination, and three were rejected; the remaining seventy passed a satisfactory examination and received the license of the board. The rejections were 4.1 per cent. The examinations were held in June and September, at the Capitol building, in Trenton. The percentage of rejections was lower this year than at any time since the organization of the board in 1890, showing that recent candidates have been prepared with greater care and thoroughness.

An Epidemic of Scarlet Fever is reported to prevail in Thorofare, a small New Jersey town.

Jefferson Medical College.—Mr. James P. Townsend has been elected a trustee, to succeed his father, recently deceased. Dr. H. F. Harris has been elected bacteriologist to Jefferson Hospital. A committee of the trustees has been appointed to represent the college at the unveiling of the monument erected to the memory of the late Prof. Samuel D. Gross on May 5th at Washington. The presentation address will be delivered by Dr. Claudius H. Mastin, of Mobile, the unveiling will be by Miss Horwitz, a granddaughter of Professor Gross, the reception by Surgeon-General George M. Sternberg, U.S.A., and an address will also be delivered by Dr. William W. Keen, professor of surgery in Jefferson College.

The Boycott of the Pan-American Medical Congress.—For some inscrutable reason, the Pan-American Medical Congress, lately held in Mexico, has been boycotted by the American medical press. The only journal which reported the proceedings was the New York Medical Record. Our contemporary in pointing out this fact admits that it cannot understand the reason of the universal silence. If the meeting of the congress was to be of no service to the profession, why was it ever decided to hold it in Mexico? Surely, the proceedings were of some value, and if so, why again, we say, have they not been reported? —*The Medical Press.*

The University of Rome was closed the 1st of this month because of the riotous conduct of the students. They have been in a more or less disturbed condition ever since the beginning of the term on November 14th. At that time an address was delivered by the professor of moral philosophy, Signor Labriola, in which the speaker denounced the minister of public instruction, who was present with him on the dais, most bitterly for his political action. The students applauded Signor Labriola and loudly hissed Signor Gianturco, the minister of public instruction, as he passed them on his way out of the hall.

The British Medical Association Meeting.—Dr. Roddick, of Montreal, the president-elect of the British Medical Association, was recently in London to discuss the arrangements for the annual meeting in August. While there he was entertained at dinners by some members of the council of the association at the Grand Hotel. The prospects of a successful meeting are bright, and we are sure it will not be the fault of the Canadians if it is not a success in every way.

Drugs Made in Germany.—The *German Pharmaceutical Journal* estimates that one hundred and seventeen new drugs have been brought on the market during the second half year of 1896.

Interhospital Football Contests take place each year between the staffs of the various London hospitals. After the games are over, the uninjured exercise their newly acquired surgical skill in patching up their maimed and battered comrades.

The S. D. Gross Statue.—A statue of the late Dr. Samuel D. Gross, modelled by Mr. A. S. Calder, has recently been cast in Paris. It is to be erected on the grounds of the Smithsonian Institute, near the Army Medical Museum, in Washington. The statue is the gift of the American Surgical Association, and Congress has appropriated $1,500 for the pedestal. The statue will be unveiled during the congress of American physicians and surgeons in Washington in May.

A Modified Diphtheria Antitoxin.—In an article published in the last number of *Fortschritte der Medicin*, Professor Behring explains modifications which he is on the point of introducing in his antitoxin serum. The serum is in future to be brought into the form of a solid. It will not contain any carbolic acid or other antiseptic, and Behring maintains that thus modified it will keep for any length of time without losing its efficacy, and that it will be free from any dangerous by-effects.

Gives His Salary to Charity.—The Earl of Derby, who is mayor of Liverpool, does not draw his salary of $10,000 but he directs the corporation to hand it over in various proportions to the hospitals and dispensaries of the town.

Navy Department, Bureau of Medicine and Surgery, Washington, D. C.—Changes in the medical

corps of the United States navy for the week ending February 6, 1897. January 30th.—Assistant Surgeon H. La Motte granted sick leave.

Changes in the Woman's Hospital. — We are so accustomed to regard this time-honored institution as a model of conservatism that the announcement of its adoption of the *fin-de-siècle* mode of treating its attending staff will be received with considerable surprise by the profession. If, as we are credibly informed, certain of the assistant surgeons (whose ability and experience are well known) have been summarily dropped from the active list at the recommendation of the medical board, we are forced to conclude that the recent progress (?) of the hospital is in a retrograde direction. The assurance that the changes are made purely "in the interests of the service" does not alter the fact that these gentlemen have, to say the least, not been treated with the consideration which they deserved at the hands of their associates.

Philadelphia County Medical Society.—A stated meeting of the Philadelphia County Medical Society was held on January 28th, the newly-elected president, Dr. James Tyson, assuming the duties of his office. The retiring president, Dr. J. C. Wilson, delivered an address dealing with the events of the past year. Dr. E. L. Vansant made a report of the results of a bacteriologic investigation of the nasal mucus in one hundred cases of chronic nasal discharge, with special reference to the presence of the Klebs-Loeffler bacillus. The cases were mainly instances of various forms of rhinitis, and the examinations disclosed the presence of diphtheria bacilli in thirty of one hundred and thirteen cultures made. In many of the others staphylococci and other bacteria were found. Dr. Solis-Cohen presented a communication entitled "The Schott Method of Gymnastics in the Treatment of Heart Disease, with Report of a Case," and a demonstration of the exercises was given by Dr. Charlotte West. Dr. A. J. Downes exhibited a portable cylinder of acetylene gas for surgical illumination: also a wound retractor and a double-bladed wire vaginal speculum.

The Sheppard Asylum.—Dr. Charles M. Franklin, of Lancaster, Pa., has been appointed first assistant physician of the Sheppard Asylum, of Towson, Md.

Dr. William M. Leszynsky has been appointed consulting neurologist to the Manhattan Eye and Ear Hospital.

The Cumberland County (N. J.) Medical Society convened at the Hotel Cumberland, January 12, 1897, at 2:30 P.M., with the president, Dr. D. H. Oliver, in the chair. Dr. L. L. Hand, of Leesburg, read a paper on "Indigestion." A report on the "Advance of Surgery for the Past Year" was made by Dr. Joseph Tomlinson, and Dr. Stites reported on "Pathology." The society adjourned, to meet at the same place on the second Tuesday in April.

Bequest to a Medical College.—The will of Prof. William H. Pancoast, who died on January 5th, directs that his museum of anatomy and surgery, together with $600 per annum, be given to the Medico-Chirurgical College of Philadelphia.

Cigarettes in Stamford.—Some people in Stamford, Conn., have become alarmed by the discovery that a large number of cigarettes are consumed in that city each week. One dealer says that he disposes of fifty thousand cigarettes weekly, and these sales, with those of other local dealers, bring the total number sold up to one hundred thousand weekly.

The Hudson Street Hospital.—The work of this institution increased largely in 1896 over that of former years. During the year 1896 the number of patients admitted to the reception ward was 2,956; new cases of out-patients treated, 26,390; total number of visits to out-patients, 72,735; ambulance calls taken, 3,532; operations in wards, 156; operations in out-patient department, 2,599. The work thus far this year has been largely in excess of the corresponding period last year.

New York State Medical Association.—The thirteenth annual meeting of the fifth district branch of the New York State Medical Association will be held in Brooklyn, on Tuesday, May 25, 1897. All fellows desiring to read papers are requested to notify E. H. Squibb, secretary, P. O. Box 760, Brooklyn.

Allegheny County (Pa.) Medical Society.—At the annual meeting of the Allegheny County Medical Society, held at Pittsburg, Pa., on January 28th, Dr. H. C. Wood, of Philadelphia, delivered an address on "Pain from a Diagnostic and Therapeutic Point of View."

Preparations for the Plague.—Dr. H. C. Boenning, quarantine physician at the port of Philadelphia and executive officer of the Pennsylvania State quarantine board, has given orders that the quarantine measures enforced at the port of Philadelphia during the prevalence of cholera in Europe a few years ago and its threatened introduction into this country will be now enforced against any vessel that may arrive at the quarantine station from the plague district, and no vessel will be allowed to come to the port of Philadelphia that can be in any way a menace to the health of the community. Rags coming from infected districts will be strictly prohibited from entering the port, as will also all articles that have been in household use, rugs, etc., which might possibly be carriers of infection. The secretary of the Pennsylvania State board of health, Dr. Benjamin Lee, will issue a circular indicating the necessity of unusual activity on the part of municipal authorities throughout the State for placing their respective towns and boroughs in a state of extreme cleanliness. The board of health will also urge the importance of attention to personal hygiene and cleanliness, especially on the part of those who may be exposed to the contagion. A communication will be addressed to the managers of the leading passenger railroads throughout the State, indicating the possible necessity for the establishment of hospitals and quarantine stations at the State line. Special in-

structions will also be issued to the inspectors at the ports of Erie and Pittsburg, as to the necessity for keeping a close watch upon any vessels arriving from foreign or domestic ports at which infection exists. The importance of the disinfection of mail matter coming from infected districts will be urged upon the postal department.

The Dispensary Abuse in Zululand.—A correspondent of *The Lancet*, writing on medical practice in Zululand, says that some of the district surgeons increase their incomes to the extent of £50 a year, by conducting a dispensary at which they must attend all natives at a uniform fee of one shilling. The shilling goes to the government, which supplies the necessary medicines; the district surgeon, however, is expected to provide surgical instruments. The dispensary system does away with all chance of native practice, which before its institution used to yield a fair income, as the natives cannot see why they should pay more than one shilling for private attendance when they can have attendance and medicine at the surgery for that sum.

Albany Medical College Alumni Association of Greater New York.—The second annual banquet of this society was held at the Hotel Savoy, this city, Thursday, January 21st. There were between fifty and sixty present and the speeches were of a very rare and pleasing nature. The association has nearly doubled in members since the last meeting, and the banquet was pronounced an even greater success than last year.

Pathological Society of Philadelphia.—A stated meeting of the Pathological Society of Philadelphia was held on January 28th. Dr. Frank White presented a foreign body from the stomach of a boy. The patient was a low-grade imbecile, who had acquired the habit of eating bits of wood and the like. He had a preference for liquid and semi-solid food, but manifested no special symptoms of gastric disturbance. The firmly matted collection of strands of wood fibre occupied almost the entire cavity of the stomach, to the form of which it had adapted itself. Dr. White exhibited also a specimen of tuberculosis of the larynx. Dr. Samuel M. Hamill presented for Dr. J. A. Johnston, of the National Soldiers' Home, specimens of tuberculous kidneys. Dr. D. D. Stewart presented an enormous obliterated aneurism of the innominate artery from a patient who had died of cerebral thrombosis in consequence of endarteritis. The successful result had been brought about three and a half years before death by the introduction into the aneurismal sac of a coil of gold wire through which was passed a strong galvanic current for more than an hour. The lumen was almost if not entirely occluded. Dr. D. L. Edsall presented a specimen exhibiting two successive perforations of the bowel in typhoid fever, and a second specimen exhibiting a single perforation in the same disease. In the first instance it was thought that the rupture had taken place during the administration of a cold bath, but when the condition was recognized with certainty it was deemed too late for operative interference. In the second instance the condition of the patient when he came under observation was considered counter-indicative of operation. Dr. William E. Hughes exhibited a perforated duodenal ulcer and a retroperitoneal sarcoma. The most striking feature of the latter was the early development of a condition resembling varicocele. Dr. W. G. Spiller presented for Drs. White, Llewellyn, and himself two interesting brains from cases of status epilepticus. In the one there existed several circumscribed areas of cortical sclerosis, and in the other an immense cyst in the occipital lobe. Dr. Alfred Stengel exhibited a large amœbic abscess of the liver, in conjunction with ulcerative colitis, and demonstrated amœbæ in stained preparations. Dr. M. H. Fussell exhibited an aneurism of the aorta at the junction of the ascending and transverse portions of the arch, which had ruptured into the right pleural cavity. Dr. Alfred Stengel exhibited a gummatous liver and also thrombosis of the left auricle and ventricle.

Philadelphia Medico-Legal Society.—At the annual meeting of the Medico-Legal Society of Philadelphia, the following officers were elected for the ensuing year: *President*, Dr. William H. Ziegler; *Vice-President*, Drs. John H. Dripps and Edwin B. Wheeler; *Treasurer*, George M. D. Peltz; *Secretary*, Dr. George Y. Pascoe.

The Board of Health Censured.—At an inquest held recently in the case of a woman who had died of post-partum hemorrhage while under a midwife's care, the coroner's jury brought in a verdict in which they censured the board of health for granting licenses to midwives without examinations. The health board, however, does not license midwives. It registers them, though there is no law compelling a midwife to register. The health board registers any midwife who brings a diploma from a school of midwifery or a note from a reputable physician that she is competent.

The Health of Dublin.—Various epidemic diseases are prevailing to an unusual extent in Dublin. Scarlet fever has been epidemic for some time, and the number of cases of measles is steadily increasing. Typhus prevails to a considerable extent, and smallpox has been reported to the authorities. The beriberi epidemic at the Richmond Asylum is subsiding. In all there have been one hundred and fifteen cases, with seven deaths.

Dr. Alexander C. Abbott, professor of hygiene in the University of Pennsylvania, has been appointed chief of the bacteriological division of the Philadelphia bureau of health, in succession to Dr. B. Meade Bolton, resigned.

The Health of the British Army in India.—The secretary of state for India stated in Parliament a few days ago that five hundred and twenty-two per thousand of the British forces in India were at present incapacitated by disease, chiefly venereal, although he maintained that the average permanent incapacitation due to disease was only forty-six men per thousand. He said that a department committee was now inquiring into the subject.

Reviews and Notices.

BRAIN: A JOURNAL OF NEUROLOGY. Edited for the Neurological Society of London by A. de NATTEVILLE. London: Macmillan & Co. New York; The Macmillan Company. 1896.

THIS summer and autumn number covers no less than four hundred and fifty-eight pages and presents a long list of deep original articles, clinical cases, critical, digest, etc.

REPORT OF THE SURGEON-GENERAL OF THE ARMY TO THE SECRETARY OF WAR. For the fiscal year ending June 30, 1896.

THIS volume contains valuable statistical data relating to health in the army and kindred matters.

WATER AND WATER SUPPLIES. By JOHN C. THRESH, D.Sc. London, M.B. Victoria, Ph.D. Cambridge; Medical Officer of Health to the Essex County Council, etc. London: The Rebman Publishing Company (Limited), 11 Adam street, Strand. Philadelphia: W. B. Saunders.

ONE of the chief aims of this work is to furnish to all interested in public and private health the information necessary to the correct formation of opinion in matters pertaining to wholesome water supply. Sufficient technical and scientific data are incorporated to enable one to take intelligent action upon plans and schemes for supplying communities of any size. The subject is most important, and it seems to us such a work has a large field of usefulness open to it. It is especially fitted for the use of those interested in wells and water supplies in small places and rural districts.

A PRACTICAL TREATISE ON MEDICAL DIAGNOSIS. For Students and Physicians. By JOHN H. MUSSER, M.D., Assistant Professor of Clinical Medicine in the University of Pennsylvania, etc. Second Edition, Revised and Enlarged. Illustrated with 117 Woodcuts and 14 Colored Plates. 8vo, 938 pages. Lea Brothers & Co. 1896.

PRACTICABILITY is one of the crowning features of this work, and completeness is another. The author's experience at the bedside has taught him that what the practitioner requires is an aid to diagnosis at every stage of a disease and in every complication. No work can possibly cover all the changes which disease processes undergo, but the result here presented shows what can be done in this direction. Several of the colored plates which have been added, as well as new woodcuts add to the book's practical worth. Of the former there are nine and of the latter fifteen. A page covered with illustrations of the malarial plasmodium is highly instructive, showing the development, process of cleavage, and isolation of the spores. The illustrations of urinary casts add much to the clearness of this chapter, and Plates I. and II., showing tube cultures of various bacilli and cocci and their microscopic appearances, are for the most part quite accurate. As a student's guide, as well as a practitioner's aid, it has much to recommend it.

DEFORMITIES: A TREATISE ON ORTHOPÆDIC SURGERY. Intended for Practitioners and Advanced Students. By A. H. TUBBY, M.S. London, F.R.C.S. England; Assistant Surgeon to and in charge of the Orthopædic Department, Westminster Hospital; Surgeon to the National Orthopædic Hospital; Surgeon to Out-Patients' Evelina Hospital for Sick Children; Joint Honorary Secretary, British Orthopædic Society; Late Senior Demonstrator of Physiology, Grey's Hospital.

THE volume, which contains something less than six hundred pages, shows the results of painstaking and conscientious work on the part of the author, although nothing strikingly new is presented to those acquainted with the modern practice of orthopædic surgery. While there are quotations in most of the chapters from the writings of Americans, we regret to see that so little space is given to the diseases of bones and joints, although the author states in his preface that "the practice of orthopædic surgery in England does not include such as tuberculous ostitis and arthritis of the hip and knee, on what grounds it is difficult to understand."

The chapter on the repair of tendons can be especially commended to those interested in the operative treatment for infantile paralysis, although only the case by Winklemann is alluded to in this connection.

Aside from these shortcomings, the book we believe will be appreciated by both general and orthopædic surgeons because of the succinct style of the writer in presenting facts, together with the profuseness and excellent quality of the illustrations.

TRANSACTIONS OF THE ASSOCIATION OF AMERICAN PHYSICIANS. Eleventh Session, held at Washington, D.C., April 30 and May 1 and 2, 1896. Volume XI. Philadelphia: Printed for the Association.

THIS volume contains many highly instructive papers well illustrated. It is neatly bound and reflects credit upon the secretary, Dr. Benjamin Lee, while the high order of the society's work is well represented.

TWENTIETH CENTURY PRACTICE: AN INTERNATIONAL ENCYCLOPEDIA OF MODERN MEDICAL PRACTICE. By Leading Authorities of Europe and America. Edited by THOMAS L. STEDMAN, M.D., New York City. In Twenty Volumes. Vol. VII., "Diseases of the Respiratory Organs and Blood, and Functional Sexual Disorders." New York: William Wood and Company.

THE full scope of the subject matter of this volume is not adequately represented in the title-page announcement, since we find in the table of contents not only chapters upon the diseases of the mediastinum and diseases of the diaphragm, which are indirectly, to be sure, closely identified with respiratory affections, but also articles upon rachitis and chemical and microscopical examination of the urine.

The respiratory affections here treated of include only pleurisy, asthma, and hay fever. We infer, therefore, that the editor's intention must be to devote one or more entire volumes to a consideration of the other affections of the lungs. Otherwise it would seem strange to find classed together these affections and the functional disorders of the sexual apparatus, for, while there is a connection between disordered respiration and sexual function, it is more apt to be physiological than pathological.

It is fair to presume that the editor knows best how to arrange his subjects so as to get them all crowded into the limited space of twenty volumes, so we will reserve judgment. After all, it is the quality of the various chapters, much more than their location, which interests us.

The first contribution of one hundred and twenty-five pages is from the pen of Dr. Herbert B. Whitney, of Denver, upon "Diseases of the Pleura." The able manner in which the various forms of pleurisy, their complications and sequelæ, as well as malignant and other growths of the pleura, have been treated in this article indicates a thorough familiarity with the subject, both theoretical and practical. The bibliography includes subdivisions for pneumothorax and malignant disease.

The next chapter, on "Asthma," is by Dr. Franz Riegel, of Giessen. Those who remember this author's "Bronchial Asthma" in Ziemssen's Encyclopedia need not be told that the quality of work is of high order. The bibliography, though brought down only from 1876, occupies three pages. Two short chapters on "Diseases of the Mediastinum" and "Diseases of the Diaphragm," both by Dr. E. Main, of Paris, include about all that can be said in these departments and bring us to the important contribution from Dr. Alfred Stengel, of Philadelphia, upon "Diseases of the Blood," to which about three hundred pages have been devoted. This is a most instructive article, and containing so much that is quite modern it offers entertaining as well as instructive reading. The subdivision upon clinical methods of examining the blood will be found a feature of practical value. "Rachitis" has been ably written by Dr. Jules Comby, of Paris, whose suggestions as to prophylaxis and treatment are especially good. The "Disorders of Menstruation" have a joint authorship, Dr. Ernest W. Cushing and Dr. Charles G. Cumston, both of Boston, having accomplished the task of telling all about them in twenty-eight pages—a more difficult accomplishment than if two hundred and twenty-eight had been devoted to it. It is fortunate that there is nothing to criticise, for we should not know which writer to blame. "Functional Disorders of the Male Sexual Organs" have been discussed by Dr. Charles W. Allen, of New York, in a dignified and clear manner. His suggestions as to prophylaxis in onanism may or may not find favor. The usual subdivisions "impotence," "spermatorrhœa," and "sterility" have been made. The short bibliography contains only the authors quoted in the text. Though coming at the last, Dr. James M. French's

"Chemical and Microscopical Examination of the Urine" is by no means least. It covers one hundred and seventeen pages, and contains enough good practical working information to repay any one for the shelfroom accorded the volume. In points of literary and scholarly merit Volume VII. is not behind those which have gone before.

AN AMERICAN TEXT-BOOK OF APPLIED THERAPEUTICS FOR THE USE OF PRACTITIONERS AND STUDENTS. Edited by J. C. WILSON, M.D., Professor of the Practice of Medicine and of Clinical Medicine in the Jefferson Medical College; Attending Physician to the Hospital of the Jefferson Medical College, to the German Hospital, and to the Pennsylvania Hospital, Philadelphia. Assisted by AUGUSTUS A. ESHNER, M.D., Professor of Clinical Medicine in the Philadelphia Polyclinic; Attending Physician to the Philadelphia Hospital. Philadelphia: W. B. Saunders. 1896.

THE book is one dealing with medical therapeutics only, no purely surgical diseases being considered, although the manipulations that may be demanded in emergencies arising in the course of various affections, such as intubation in diphtheria, are sufficiently described. An excellent index renders the mass of material contained in the thirteen hundred pages of the volume readily accessible to the hurried reader. The book is well printed and substantially bound.

DIAGNOSTIK DER HARNKRANKHEITEN. ZEHN VORLESUNGEN ZUR EINFÜHRUNG IN DIE PATHOLOGIE DER HARNWEGE. Von PROF. D. C. POSNER, in Berlin. Zweite verbesserte Auflage. Berlin: Verlag von August Hirschwald. 1896.

THIS second edition of Posner's excellent little work has been added to and somewhat improved. There are forty-four illustrations in the text, and an appendix gives a short symptomatology of the common diseases of the urinary tract which will be found useful.

ELEVENTH ANNUAL REPORT OF THE STATE BOARD OF HEALTH AND VITAL STATISTICS OF THE COMMONWEALTH OF PENNSYLVANIA.

A HEAVY volume of seven hundred pages, containing numerous reports upon water courses and the supplies of cities, with many maps showing sources of pollution; reports of laws bearing upon health, vital statistics, and a mass of information on various topics.

THE TONIC TREATMENT OF SYPHILIS. By E. L. KEYES, A.M., M.D., Late Professor of Dermatology, Syphilology, and Genito-Urinary Surgery in the Bellevue Hospital Medical College, Consulting Surgeon to the Bellevue Hospital. Revised Edition. New York: D. Appleton & Co. 1896.

UNLIKE most revised editions, it cannot be said of it that it has been brought up to date. This little work has, in this sense, nothing to do with what has been written by others. It is an exposé of the author's own particular views upon the manner in which mercury should be given in curing syphilis, and in an experience of twenty years since these views were first advanced by him he has found no reason for changing them. Much additional information upon local and general treatment will be found, although there are but seventy-eight pages in all.

PTOMAINS, LEUCOMAINS, TOXINS, AND ANTITOXINS; OR, THE CHEMICAL FACTORS IN THE CAUSATION OF DISEASE. By VICTOR C. VAUGHAN, Ph.D., M.D., Professor of Hygiene and Physiological Chemistry in the University of Michigan, and Director of the Hygienic Laboratory; and FREDERICK G. NOVY, Sc.D., M.D., Junior Professor of Hygiene and Physiological Chemistry in the University of Michigan. Third Edition, Revised and Enlarged. Philadelphia and New York: Lea Brothers & Co. 1896.

PATHOGENIC germs are, in these days, at the bottom of all poisoning in infectious disease, and since of late the very toxins of these agents have been utilized to combat their intoxicating effects, a work of this kind is not only a desideratum but it becomes a necessity. The study of the elaboration of poisonous products has advanced with wondrous strides, and the prevention of disease by antitoxin prophylactic inoculations is too attractive to be given up because of repeated failures and disappointments. The almost daily discovery of new facts in the realms of bacteriology, and in the therapeutic action of specific chemical agents, makes the frequent appearance of a rewritten edition of such a work almost necessary. The five years' interval between the second and last editions has been crowded with new observations bearing upon the field here covered. It may be safely stated that the progressive physician of to-day requires a working knowledge of this comparatively new branch of medical science.

A MANUAL OF VENEREAL DISEASES. By JAMES R. HAYDEN, M.D., Chief of Venereal Clinic, College of Physicians and Surgeons, New York; Professor of Genito-Urinary and Venereal Diseases in the Medical Department of the University of Vermont, etc. In one 12mo volume of 263 pages, with 47 engravings. Cloth, $1.50. Philadelphia and New York: Lea Brothers & Co. 1896.

DESIGNED for students and practitioners, this work of two hundred and sixty pages covers the ground in a concise manner. The general outline of the work is based upon the larger treatise recently given out by Dr. Taylor, and the formulæ are largely drawn from the treatment recommended in the latter work. The three venereal diseases and their complications are described, as well as the various procedures of an operative nature which the latter often require. Students rather than practitioners will find this book useful.

TRANSACTIONS OF THE MEDICAL SOCIETY OF THE STATE OF PENNSYLVANIA AT ITS FORTY-SIXTH ANNUAL SESSION. Held at Harrisburg, 1896. Volume XXVII. Published by the Society. Philadelphia: The Edwards & Docker Company.

THIS record of the proceedings at the Harrisburg meeting of May last contains, besides the various addresses, a number of excellent papers and a somewhat lengthy history of the State society by Dr. William B. Atkinson, its secretary.

ROYAL INFIRMARY CLINIQUES. By ALEXANDER JAMES, M.D., F.R.C.P.E., Physician to the Royal Infirmary. Edinburgh: Oliver & Boyd, Tweeddale Court. London: Simpkin, Marshall, Hamilton, Kent & Co., Limited. 1896.

THIS is a series of lectures delivered to the class in clinical medicine, for whose students it is prepared and to whom it is dedicated. A variety of interesting diseases are described, some of the cases presenting peculiar features. There are colored plates of Addison's disease and a few minor illustrations.

RHEUMATOID ARTHRITIS: Its Pathology, Morbid Anatomy, and Treatment. By GILBERT A. BANNATYNE, M.D., Honorable Physician to the Royal United Hospital, and to the Royal Mineral Water Hospital, Bath. Bristol: John Wright & Co. 1896.

IN this excellently written treatise on a deforming and little understood disease Dr. Bannatyne suggests that the affection is of bacterial origin, and describes certain micro-organisms discovered and studied by Drs. Wohlmann, Blaxhall, and himself, which he believes to be specific to the disease. He makes a very proper distinction between senile arthritis and arthritis deformans. The work is thoroughly modern, even to the presentation of a skiagraph of the hand showing the deformities of the skeleton in arthritis deformans.

A PRACTICAL TREATISE ON MATERIA MEDICA AND THERAPEUTICS. By ROBERTS BARTHOLOW, M.A., M.D., LL.D., Professor Emeritus of Materia Medica, General Therapeutics, and Hygiene in the Jefferson Medical College of Philadelphia; Fellow of the College of Physicians, etc. Ninth Edition, Revised and Enlarged. New York: D. Appleton and Company. 1896.

THIS latest edition of Dr. Bartholow's standard treatise on materia medica will be welcomed by all to whom the work has been an authoritative guide during the past twenty years. Many changes and additions have been made to bring the book fully up to the times, much of the new matter having to do with a discussion of the synthetic products of German laboratories, which he includes among the antiseptics. To those who are familiar with Dr. Bartholow's excellent work no description of it is necessary, and to others the fact that nine editions of the book have been called for since 1876 is satisfactory evidence of its appreciation by the profession.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, January 21, 1897.

JOSEPH D. BRYANT, M.D., PRESIDENT, IN THE CHAIR.

A Further Study of Tuberculous Infection of Dust.—DR. IRWIN H. HANCE read the paper (see page 217).

The Hygienic, Educational, and Symptomatic Treatment of Pulmonary Tuberculosis, with a Plea for Sanatoriums for the Poor.—DR. S. A. KNOPF read the paper (see page 222).

Sanatoria for the Treatment of Incipient Tuberculosis.—DR. E. L. TRUDEAU, not being able to leave the Adirondack sanatorium, sent a paper on this subject, which was read by DR. PRUDDEN. Experience acquired in the development of the Adirondack sanatorium during the past thirteen years might, the author thought, furnish evidence of interest as to the practicability, necessity, and safety of a special hospital for the treatment of pulmonary tuberculosis. The fact that tuberculosis in the early stages was a curable disease, and the further fact that those patients with the chronic type deserved consideration on humanitarian grounds, furnished sufficient reason for establishing sanatoria. The lot of the consumptive poor had been hard, but it had been rendered harder since the fact had been pointed out that the disease was infectious.

Sanatoria for consumptives should be located outside of large cities. The pavilion plan was advocated by Dr. Trudeau. The buildings should be free from dust, have plenty of air space, thorough ventilation, and sunlight. Since the establishment of hospitals for consumptives in England, the death rate from that disease had fallen. A fair proportion of the patients was cured. The sanatorium should be conducted so as to guard against infection and reinfection, and to give the best sanitary conditions. While no climate was a specific for consumption, still the favorable influence of certain climates had been proven. The paper briefly described the construction of the pavilions at the Adirondack sanatorium, each one containing usually about five patients. This plan enabled the patients to select for companions those who were congenial, and to avoid others. It encouraged exercise, as they had to walk out to reach the dining-room. When a patient became worse he was at once removed to a separate infirmary. They were required to live much in the open air, but Dr. Trudeau entered a strong protest against patients with abnormal temperature, increased pulse, and other signs of phthisis in active state, taking much exercise, especially such severe exercise as rowing and mountain climbing, which some advised. The use of paper cuspidors, to be burned night and morning, and other provisions made in the cottage plan to prevent infection, had proven most successful, as shown by the absence of tuberculous germs in the dust from all of the cottages except one, according to a previous paper read by Dr. Hance. In that exceptional case the patient had disobeyed instructions and had expectorated wherever it was convenient, and in general was not cleanly. Additional evidence was furnished by the significant fact that during the thirteen years since the pavilions had been established not a single attendant had developed tuberculosis. Susceptibility was enhanced by bad hygiene, such as existed in tenements, etc.

Rigid rules in the selection of cases were not easy to make, but it was safe to say that the earlier the diagnosis was made, the better the prospects of cure under treatment. The first few months often presented the only opportunity for restoring health. The apathy of the general profession in making an early diagnosis seemed inscrutable. Cases were allowed to pass as bronchitis until a cavity or hæmoptysis compelled the recognition of tuberculosis. Too much stress was placed on the absence or presence of physical signs, and not enough attention was given such symptoms as cough, sweats, etc., and frequent examination of the sputa. Inoculation of a guinea-pig might be necessary. Dr. Trudeau had seen no harm come from the use of tuberculin, either in diagnosis or treatment. It was only in certain cases that he used it for treatment, and then in doubtful cases for diagnosis. The principal aim of the modern sanatorium treatment of tuberculosis was to improve the patient's nutrition, increase the resistance to the disease by placing the patient in the best environments, in an invigorating climate, and by furnishing open-air life, rest, careful regulation of the daily habit, abundant supply of nutritious food, and such medicinal agents as might be indicated in the several cases. Living out of doors, well covered, was without danger, as shown by the fact that lobar pneumonia had not occurred in one of the many hundreds of patients who had been treated at the sanatorium. Exercise should be graduated according to the patient's strength, and especially should not be great in fever. Overexercise might light up quiescent tuberculosis. As much food should be taken as possible, consistent with assimilation. Cod-liver oil, hypophosphites, and arsenic were commonly used; creosote when it improved appetite and digestion.

In a general way, it might be said that about twenty per cent. of all cases admitted to the sanatorium were cured. In thirty per cent. or more the disease was more or less arrested. Of incipient cases, thirty to thirty-five per cent. were cured.

DR. H. M. BIGGS spoke of the work and regulations of the health department with a view to controlling tuberculosis. For the past three years the department had required the reporting of cases at hospitals and dispensaries, had requested reports from private physicians, in the case of hotels and tenements had carried out a system of inspection, and had required of owners of houses renovation of rooms in which there had been death from tuberculosis. Disinfection as ordinarily employed had been considered insufficient; hence renovation by painting, etc., had been demanded. The reports during these years showed the extent of tuberculosis in the city, for in 1896 the number of cases, far less than the actual number, had reached nearly eighty-five hundred; adding to this number those of deaths from tuberculosis, the number was thirteen thousand. At first the inspectors were almost always met with reproaches, but at present they usually found that all or a part of their regulations were being carried out before their first visit. This showed the rapid dissemination of knowledge regarding the infectious nature of tuberculosis, and the necessity for proper disposal of the sputa and observance of cleanliness, etc. Dr. Hance's investigations proved the necessity for such instruction and regulations, since in the tenements where cleanliness was observed the dust collected contained no tubercle bacilli, while that from dirty tenements occupied by consumptives had produced tuberculosis in guinea-pigs which were inoculated with it.

During the past week the health board had taken another step, which was to require physicians to report all cases of tuberculosis, as they had for years been required to report cases of contagious disease. The distinction was still made, however, that tuberculosis was not a contagious disease, but an infectious communicable disease. In addition to this, the establishment of sanatoria under control of the health department was recommended, and on the ground that it had been found absolutely impossible to remove very se-

rious sources of infection with the power which the department possessed under existing relations. It was not intended to make inspections in private houses, but in places where the health of the public was in danger, as in tenements, hotels, etc.

Dr. Biggs presented tables of death rate and deaths from tuberculosis in the city since 1867. The first ten years, until 1877, the annual death rate per 1,000 for all diseases had been from 27 to 33, while that from tuberculosis alone had been about 5. The next ten years there was a decided fall in the deaths from phthisis, it being between 3.65 and 4.27. From 1887 to 1896 it had been only 2.58. The chief fall had been since 1882, after the announcment of the infectious character of tuberculosis.

Tuberculosis was wholly a preventable disease, and he had no doubt that if the department could obtain sufficient appropriations for the establishment of hospitals and the supervision of institutions where the disease was treated, the death rate from tuberculosis would be reduced one-half the next ten years.

Regarding the suggestion in Dr. Trudeau's paper, that there was danger of tuberculosis only when there was considerable susceptibility, Dr. Biggs' belief was that the question of susceptibility was only one of degree. While some persons were unusually susceptible, yet susceptibility was very general. Further, tuberculosis was distinctly a curable disease. Even among the poorest classes autopsies showed that in a large proportion of cases tuberculosis had existed, was recovered from, and death had taken place subsequently from some other disease. It was chiefly a question of early diagnosis and favorable conditions for the treatment of the disease, to effect a cure. As to tuberculin, he had used it considerably in hospitals and had seen no ill results, and the same experience was narrated to him by Koch last summer, who had seen no harm from its use for diagnostic or other purposes in five thousand cases.

Dr. Mabbott said that while he was convinced the work of the health department had aided in reducing the death rate from tuberculosis, yet it was a question whether there had not been other factors. For instance, during the later decade the city limits had been extended nearly to Yonkers, taking in a district where there was presumably less tuberculosis. Again, probably more consumptives now left the city and died outside.

The Degree of Infectiousness of Tuberculosis.—Dr. Egbert Le Fevre thought we had been given to believe that tuberculosis was much more infectious than it was. The infection of dust from certain places had been proven by those who worked in laboratories and had injected it into guinea-pigs. But he did not believe we could correctly judge of the infectiousness of city dust by such inoculation experiments. Our bodies were protected by epithelium and by a natural resistance to the germs. When that resistance was lost we might be infected. He thought a scare had been excited in the city with regard to tuberculosis which was of unnecessary proportions. If the disease were preventable to the extent that had been suggested, there was but one course to pursue, and that was the segregation of all tuberculous patients. But were we willing to go back to seventeenth-century methods, when segregation was demanded for lepers? We would have to wall off all our consumptives. Anything short of that step would simply be playing at preventive measures. If stringent rules were going to be enforced, they must be applied to the rich as well as to the poor. Tubercle bacilli had always been present, and he believed always would be. He did not believe we were going to overcome the disease by trying to stamp out the tubercle bacilli, but rather by inculcating the laws of health, by teaching the people how to take care of themselves: not by isolating the tuberculous from the community, breaking up family, social life, and business.

It had been stated to-night that the board of health was taking measures to stamp out tuberculosis. The speaker, as a member of the medical profession and standing in relation to his patients, would like to know exactly what steps the board of health was going to take with regard to isolation, etc. Because of the hardship which came from a diagnosis of tuberculosis, he had time and time again known death certificates to be made out under acute bronchitis, pneumonia, etc., when the patient had advanced tuberculosis. When chronic tuberculosis was made a matter of public record, the insurance companies found it out and refused to pay insurance.

Regarding the separation of consumptives from others in general hospitals in the city, he believed the board of health need only say that it should be done and the commissioners of charities would make provision so that the regulation could be enforced. He did not agree, however, with the recommendation that the hospitals for consumptives should necessarily be under the board of health. The board had taken control of the hospitals for contagious disease, and this might have been proper; but tuberculosis was not a contagious disease. It could be combated by ordinary cleanliness; it did not demand special isolation. It was true that Dr. Biggs had admitted it was not a contagious disease, but the public was not in the habit of splitting hairs in distinguishing between the words infectious (or communicable) and contagious, when the same regulations were applied to both classes of cases. Only yesterday a faithful servant employed by a family for many years was compelled to leave the house, because she had a cough and the family dreaded infection.

Dr. J. E. Stubbert thought there was no necessity for frightening the people with regard to the danger of infection from tuberculosis. In the only hospital in the city for this class of patients there had not, so far as he knew, been a case of infection of attendants since its establishment. If isolation of such cases from others was demanded in city hospitals, he thought it could be carried out in a separate building on the same grounds. In the construction of sanatoria, what was needed was not one or two large buildings for numerous patients, but cottages. This was essentially an American plan, and it was a good one. The spit cups shown by one reader were not approved by Dr. Stubbert.

Committee on Tuberculosis.—After a few closing remarks by Dr. Knopf, Dr. Prudden made the following motion, which was adopted: "That a committee of eight be appointed by the chair, of which the incoming president of the academy shall be *ex-officio* chairman, to consider and to report to the academy upon tuberculosis in its relation to the public health, and measures which should be taken to curtail its ravages, and the ways in which the academy may be useful in the attainment of the object proposed."

Preparation of Blood for Microscopical Examination (sequel to paper published in the Medical Record, October 17, 1896).—Dr. H. G. Piffard read the paper (see p. 228).

Dr. Le Fevre and Dr. Vissman spoke of some of the difficulties connected with the microscopical examination of the blood, and of the value of some of the points brought out by Dr. Piffard.

SECTION ON OBSTETRICS AND GYNECOLOGY.

Stated Meeting, January 28, 1897.

W. R. Pryor, M.D., Chairman.

Officers Elected.—Dr. S. Marx was elected *Chairman*, and Dr. H. L. Collyer *Secretary* for the ensuing year.

Cystic Degeneration of the Chorion.—Dr. Marx presented three specimens. The first was a part of the curettings in a case of cystic degeneration of the chorion. As usual in such cases—they were rare, at least in New York—there had been hemorrhages almost from the beginning of pregnancy, which had continued until about the tenth week, when he saw the patient and removed the material, about a pailful, after first dilating the cervix with the hand. The hemorrhage during the operation was severe, but was controlled by a gauze tampon, which was removed after thirty-six hours.

Infection of Pregnant Uterus from the Colon.—Dr. Marx's second specimen was a uterus removed post mortem from the body of a woman whom he had delivered some days before in a hospital. He was sent for after she had been forty-eight hours in labor—rapid pulse, foul discharge from the uterus, and other signs of sepsis having developed when he was called. Following removal of fœtus and placenta, he curetted and packed the uterus; but, following the rule, septic symptoms continued and at the end of forty-eight hours he injected antistreptococcus serum. No benefit resulted, as was usual in puerperal cases according to his experience, although in surgical sepsis Dr. Gerster had told him he had had good results. At the end of six days he opened a rapidly growing tumor at the side of the uterus, which proved to be an ovarian abscess. The patient died six hours later. Autopsy showed adhesions between colon and fundus uteri, and colon bacilli and streptococci in the uterus.

Inversion of Uterus; Hysterectomy.—Dr. Marx's third specimen was a uterus removed by laparotomy for inversion. The girl had aborted at the sixth month, and on expulsion of the fœtus had herself pulled upon the cord and thus caused inversion of the uterus. Dr. Marx saw her after thirty-six hours, when sepsis already existed. She was taken to a private hospital, and preparations were made for hysterectomy, for it was deemed best to get rid of as much of the local focus of infection as possible. Attempts at reduction made previously had failed. While the abdomen was open, an assistant tried to reduce the uterus, but the tissue was so rotten that the hand went through. Another attempt was more successful. Dr. Marx found no difficulty in doing hysterectomy, and, as usual, the pulse dropped, the patient did well for a time, but after a few days died suddenly, perhaps of heart failure.

Dr. Collyer had seen one case of hydatids of the chorion. It was of a girl supposed to be five months pregnant. Usually there was in such cases much trouble from hemorrhage, especially at operation, but in this instance there was little.

Biological Basis of Menstruation.—Dr. J. Clarence Webster, of Edinburgh, was the author. He first pointed out certain explanations of the menstrual function which he regarded as erroneous. The first was its relation to ovulation, the view having become widely believed in that menstruation was a necessary preparation for the development of the ovum in case it should be fertilized. Many facts refuted this explanation. Conception sometimes took place before puberty or beginning of menstruation; it sometimes occurred after the menopause: post-mortem and ante-mortem section showed Graafian follicles at all periods of development without relation to the menstrual period, and the reverse; removal of the ovaries did not always stop menstruation. Yet it was not denied that there was some relation between the two processes—menstruation and ovulation. The author then mentioned the variable effect of operations, removing the ovaries, the tubes, etc. In the third place, he spoke of Dr. Johnstone's view, supported by Tait and some others, that the menstrual act was related to the nervous system, peripheral, or both cerebral and peripheral, and who explained cessation of the menstrual function after removal of ovaries and tubes by the tying off of the nerves, or failure to do this close to the uterus in the cases in which the flow continued. Fourthly, as to the view that menstruation was probably a preparation of the uterine mucosa for the engrafting of the ovum, the author said he had repeatedly urged its improbability on several grounds, among which he mentioned the occasional occurrence of conception before commencement of menstruation, at a time when the mucosa could not have been denuded by that process; also the occurrence of conception during lactation, when the menstrual process was in abeyance. Further, there was nothing worthy the name of menstrual decidua in the menstrual discharge. Not a single fact had been advanced to support Lowenthal's theory, that menstruation was due to non-fertilization and death of the ovum—that when the ovum was fertilized, it became implanted in the uterus and grew, and menstruation ceased; when it died, it was discharged and the mucosa broke down.

Johnstone, he said, believed that menstruation was the result of periodic wasting away of corpuscles which were too old to undergo the changes which must occur in connection with the attachment and development of the fertilized ovum. Johnstone did not regard the endometrium above the internal os as mucous membrane, but as belonging to adenoid tissue.

In the fifth place, Dr. Webster considered the relation of menstruation to body metabolism, and finally its biological aspect, which he said had been almost entirely neglected. A careful study of plants and animals had enabled biologists to establish a distinction between "maleness" and "femaleness" in terms of physiological and psychological value. It was only recently, however, that sex differences had been studied on the basis of such inquiries. Too long had reproduction and sex been considered by themselves, as if they were something to be dissociated from the general physiological organism. The most important sex distinction which had been established was that which had to do with the general metabolism or the protoplasmic chemistry of the body. Every living cell and organism was constantly representing two forms of metabolism—the one anabolic, by which nutrition was taken in, waste repaired, energy restored, structure made or altered; the other catabolic, by which potential was changed into kinetic energy, or movement or activity manifested, structural alteration induced, and waste created. Throughout the animal kingdom the characteristic metabolism of the male was catabolic; of the female, anabolic. The same distinction was made in the plant world. The lines of inquiry on which this distinction was made were as follows: 1, a study of sex; 2, investigation of the condition of animals and plants in the lowest forms in which sex had its beginning; 3, observation of normal and pathological changes in the reproductive apparatus; 4, experimental inquiry into the nature of factors which determined sex. After following up these lines of inquiry, the author thought we were forced to regard the menstrual function as the highly specialized means, gradually produced in the evolution of the highest mammals, by which the two great factors in tissue metabolism, the anabolic and catabolic, were properly balanced. Normally it became established along with the various phenomena which characterized the development of sexual activity, namely, at puberty, because it was then that the metabolic habit peculiar to females (predominance in anabolism) manifested itself. The range of variation in the menstrual function in the human female was attributed to the instability of the process during the stage of evolution preceding the fixed habit. While there could be little doubt that menstruation had been established in higher ani-

mals by gradual evolution, we were in doubt as to how it had become established. Having begun, it probably proved to be advantageous, and by natural selection became a fixed characteristic. Had it proved of no advantage, it probably would have been eliminated. Natural selection in the highest ranks of the animal world was not in the direction of establishing a numerical superiority, but was based on individual characteristics in the selected number. The tendency was to diminish the number of offspring and improve the quality of the individual. It was associated with the development of a single uterus, with a diminution in the number of the offspring, with the determination of the semi-erect or erect posture. Of prime importance among these factors was a change from a bicornuate to a single uterus. Natural selection had tended to make irregular menstruation regular, the male having a feeling of disgust for the menstruating female. In his remarks upon marriage, observed to a degree by many animals, Dr. Webster said the offspring undoubtedly stood a better chance of surviving when the parents united their efforts in raising it.

Speaking of the rut, Dr. Webster said it came on in different animals at different seasons of the year, in accord with the duration of pregnancy, this terminating at that season which offered the best chance for the offspring to survive. In man and in some animals season was less important for the raising of the young, and copulation took place throughout the year. It seemed likely that the rut in the higher vertebrates was an expression of forced sexual affinity to secure fertilization of the ovum. The physical changes at this season pertained mostly to the male, who showed great activity, while in the female the change was mostly psychical and passive, being in accordance with the rule already referred to—that in the female the anabolic process was typified, the catabolic in the male.

Dr. Arthur Johnstone, of Cincinnati, opened the discussion. He said he had for years been working along this line; that ten years ago he stood almost alone, but he was glad now to see this confirmation of his labors. Many of his listeners were familiar with the papers which he had published, but he wished to refer to one which he had read before the Chicago Gynecological Society, in which he attempted to analyze the functions of reproduction, ovulation, and rut. Cook, of the Parry expedition to the Arctic regions, had given an account of a settlement of Esquimaux, which confirmed some of his views and those expressed in the paper to-night. During the long winter, which was continuous night, these Esquimaux women not only lost sexual appetite, but ceased to menstruate, and their physical condition was so lowered that they became exhausted on slight exertion. With the return of day menstruation returned, they became highly active, and the sexual feeling manifested itself in strong degree. Dr. Johnstone believed the rut depended upon the physical condition, and was the manifestation of perfect physical development. Ovulation and menstruation were not coincident; they ran on different times, although the times might coincide. Regarding menstruation, he would take a little more radical ground than the author; he would go farther back, and say that menstruation began when the first leaf fell off the first tree. Menstruation was nothing but a shedding. As far back as animal and vegetable life went, that law of shedding was one of the first things to manifest itself after epithelium had been produced. Leaves were epithelial structure, they performed their function, they fell. The crab dropped its shell, snakes shed their skin, birds moulted. In all this we saw the exact reproduction of menstruation. Referring to what had been spoken of as the Stevenson wave, he said Dr. Mary Putnam Jacobi may have been wronged in using Stevenson's name in this connection, since she had first spoken of the phenomenon. It had, however, been dropped until Stevenson had written regarding it. Menstruation was simply a shedding—a shedding of structures which had become useless. In the lower animals the shedding took place through the lymphatics; animals in the upright position menstruated in the strict sense of the term. Investigators who had looked into his work had not made allowance for the rut in the human being, always present. Man was the only animal on earth in which it was always present. The necessity for it was easily seen; it was the one thing which held society together. It was the cement, the life of the nation. The endometrium had to be kept in a higher condition than in animals, higher than in monkeys. The human being upright, there was nothing to support a soft uterus, in which menstruation took place through the lymphatics: consequently the organ was firm and the menstrual blood poured into it occasionally and was washed away. Dr. Johnstone thought there was close relationship between the nervous system and menstruation, and that the arrest of menstruation after operations was due to cutting off the nerve supply. He believed future advance of gynecology was going to depend largely upon a study of the menstrual wave. It was the best barometer known to him of the female organism, its ills and whims. A friend of his was studying the urea or chemical wave, which promised much also.

Credit Wrongly Placed.—Dr. Mary Putnam Jacobi said she thought she had been unlucky with regard to the one idea which she might claim to have added to our knowledge of this subject. Dr. Johnstone had referred to the wave, and stated that she had left the idea undeveloped. After reading the article of Stevenson, to whom the credit had been given, she had been unable to find anything which had not been established in her article in 1876. The wave was established particularly with reference to the variation in the quantity of urea, of which she had given many tables, and also with regard to the pulse pressure. German observers were following in these lines, and had given her credit. Dr. Jacobi had found the remarks of Dr. Webster and of Dr. Johnstone on the insufficiency of the lymphatic mechanism of the uterus to carry away the detritus in certain animals, including woman, exceedingly interesting. She believed it was Leopold who had described the mucosa of the uterus as primarily of lymphatic construction. The precise mechanism by which the accumulation of blood was diverted to the great mass of tortuous blood-vessels around the tubes and ovaries had not, she believed, been touched upon by either of the speakers. In her essay referred to, she had suggested that this vascular system was comparable to the nodes on the stems of plants, in which it was known that material accumulated to provide for the new growth of the stem. In a biological sense the analogy was perfect, and it was almost perfect in a mechanical sense. Dr. Jacobi would trace the nervous mechanism to the brain, and mentioned the inability for mental work in amenorrhœa, and the existence of the latter in nearly all cases of chronic insanity. Dr. Jacobi thought it was an error to say that anabolism applied exclusively to the female organism. What had been said in this line applied to the female cell, but not to the female organism, which must necessarily embrace both male and female characteristics.

Dr. Bernard Gordon was disposed to accept the view of a German writer, that the uterus and tubes only acted the part of a glandular duct, the ovary being the gland. When the ovaries were removed menstruation ceased in most cases, and the uterus atrophied because it was no longer needed. The fact that the descending ova did not always become implanted

and grow had its analogy throughout nature, for did not hundreds of acorns rot where but one grew?

Dr. Tull asked a question based on the observation that when both ovaries were removed a flow soon took place in nearly every instance, whereas it hardly ever occurred after removal of but one ovary.

Dr. Edward A. Ayers thought a good many things were explained in connection with the menstrual function and ovulation by bearing two things in mind: 1. That in the matter of reproduction nature made provision for a great excess, so as to insure perpetuation of the species. 2. Everything developed sooner or later into rhythmic action, and so with menstruation. By this function it seemed nature's purpose to sustain a constant fresh supply of more embryonic form of tissue, a younger and more potential form of protoplasm.

The author closed.

OUR LONDON LETTER.

(From our Special Correspondent.)

THE QUEEN'S SPEECH—MEDICAL MATTERS — DR. RENTOUL'S CAMPAIGN—INFANTILE CEREBRAL DEGENERATION—THE LATE DR. MONAT AND DR. BALLARD —DIPHTHERIA—DUBLIN EPIDEMICS — VACCINATION INJURIES—DR. RODDICK, OF MONTREAL

London, January 22, 1897.

The Queen's speech is rather disappointing to sanitarians. It was quite expected that some action on the report of the vaccination commission would be taken, but the subject is not mentioned. There is a reference to "provisions for adding to the military defences of the empire," which I suppose means increasing the army, but there is no indication of improving the medical service, and yet the deficiency in this department continues to be a scandal. The Queen is made to state that her government is directed to "take the most stringent measures" against the spread of the plague, and no doubt the precautions already adopted in our ports will be continued, whatever else may be done. The newspapers report that this government has consented to be represented at an international conference proposed by some of the powers on this subject. Malta has declared a strict quarantine, and this retrograde step may perhaps be followed by other Mediterranean authorities, so that the English system may again have to be defended in the conference. In our own ports we are not likely to deviate from the plan that has been so successful in keeping out cholera. Bills are promised on inebriates' reformatories and on employers' liability, both of which must interest the profession. Another bill of great importance is promised, viz., for improving the London water supply.

Dr. Rentoul signalizes his election to the General Medical Council by publishing a spirited address on the most important subject of medical politics at the present day, the one that he has devoted so much of his time and money to prevent being settled in a way to injure the profession and endanger the public. He asks whether it is in the best interests of public health and public safety that the proposal to provide the poor with midwives should be opposed, and if so, how are midwives to be done without? And he answers these questions in a manner to commend the address to every general practitioner and to bring shame and confusion to the few consultants who have supported a traffic in sham midwifery diplomas. He shows from statistics how frightful has been the loss of life under midwives, and that there is no difficulty in providing qualified medical assistance for every poor woman in labor. Thus he cuts away the superfine sentiment on which so many have been trading, and then proceeds to refer in some detail to the means by which every poor pregnant woman can, with the utmost facility, secure the services of a qualified practitioner and a practical nurse for her confinement. The conditions for this are now in existence, and so far there is no necessity for legislation. It seems, therefore, to me the more monstrous that the neglect of them in a certain proportion should be put forward as a reason for creating an inferior order of practitioners.

Dr. Rentoul's trenchant manner of dealing with the midwives question has given rise in some quarters to the notion that he is naturally fond of controversy, and this impression was fostered during the election by interested opponents. I am, however, assured by one who has lived in closest connection with him that this is a complete mistake, and that he is by nature a most modest unassuming man, who is only driven to fight this question by the clearness with which he sees the dangers ahead and the conviction that it is the duty of the day to speak out and manfully press home the truth. The Medical Council, therefore, need not fear the entrance of a mere noisy demagogue to rouse it from slumber, but prepare to welcome a sincere advocate of the well-being of the public and profession, who was elected at the head of the poll to represent his brethren. There is one thing in his address I cannot help regretting. Having asked the several medical societies to adopt a resolution, he remarks that if the majority of practitioners object he would have to drop this most vital question as their representative, while if they adopt it he can tell the council fearlessly that he speaks for and in the name of his constituents. Now he can thus speak already. He is returned at the head of the poll in the manner appointed by Parliament, and there can be no necessity to strengthen his position by any further plebiscite. Remembering, then, the apathy of the constituency, I feel it unwise to ask it to take the trouble to repeat its vote, and I hope Dr. Rentoul will hold tenaciously the position he has won, and boldly assert his right to speak in the name of the profession which has elected him to defend its interests.

A somewhat difficult subject was illustrated by lantern slides at the last meeting of the Medico-Chirurgical Society. I scarcely know what some of the bygone fellows would have thought of a magic-lantern entertainment at a medical society, but perhaps as soon as convinced of the utility of any mode of conveying information they would have accepted it. The subject was infantile cerebral degeneration, with symmetrical changes of the macula. Four cases were reported in the paper by Drs. Kingdon and Risien Russell, and another case was observed by Dr. F. J. Smith. All the recorded cases have been in Jewish children, some of them more than one in a family. This rare disease usually begins with muscular enfeeblement and failure of sight, when the child is about three months old. A month or two later characteristic changes in the region of the macula lutea may be observed with the ophthalmoscope. The child becomes apathetic, unable to sit up, and when lying down cannot turn from side to side. Blindness approaches; there are muscular atrophy and general emaciation; the heart, lungs, and abdominal viscera are normal, and the thermometer gives no sign. But the paralysis deepens into death, which occurs at from one and one-half to two and one-half years. At the lutea the symmetrical changes are a whitish-gray patch, slightly raised above the surface of the retina, with a few visible vessels at the periphery. The fovea centralis is seen as a dark-red spot in the centre of the patch. At first the papilla shows no definite change, but later there is distinct optic atrophy. Widespread degener-

ation of the fibres of the corona radiata and the pyramidal tract throughout the pons, medulla, and cord constituted the chief lesion found post mortem, but similar extensive degenerative changes were found in the fillet, descending root of the fifth, and superior cerebellar peduncles. All these changes were symmetrical. Photographs of the children at different periods were exhibited to show the clinical progress, and photo-micrographs of the preparations to show the changes found after death, both in the central nervous system and in the eyes. Sections were also shown under the microscope.

The death, at the age of eighty, is announced of Dr. F. J. Monat, formerly inspector-general of prisons and visitor of asylums in Bengal. He had also served in other high offices, among them physician of the Calcutta Medical College and secretary of the Council of Education. Of late years he was better known for his valuable contributions to the Statistical Society, of which he was president, 1890–92.

Another noteworthy death is that of Dr. Edward Ballard, F.R.S., many years inspector of the local government board, in which position he carried out a number of very important inquiries. He died on Tuesday, in his seventy-ninth year.

There is a fall in the diphtheria mortality this week to fifty-two, but this number is seventeen in excess of the average for the decade.

Measles is increasing but scarlatina decreasing in Dublin, where, however, whooping-cough is rife.

Drs. Thorne Thorne and Monckton Copeman seem to be having a good time on the continent. They are sent to study the systems of vaccination, and the authorities and medical men are giving them every assistance for inspecting and carefully studying the arrangements. Perhaps the government is waiting for their report before determining whether to take action.

Dr. Roddick, of Montreal, was entertained at a dinner here on Wednesday, as president-elect of the coming meeting in Canada of the British Medical Association.

OUR PARIS LETTER.

(From our Special Correspondent.)

THE NEW LAWS REGARDING THE STUDY AND PRACTICE OF MEDICINE IN FRANCE CAUSE CONSIDERABLE DIMINUTION IN THE NUMBER OF STUDENTS AND DOCTORS, BOTH FRENCH AND FOREIGN—LEGISLATION FOR CHILDREN ENGAGED IN INDUSTRY—PRIZES FOR 1899 OFFERED BY THE ACADEMY OF MEDICINE—QUININE AND ITS ANTIDOTE, ATROPINE—THE RADIOGRAPH ALTERS PROFOUNDLY A DIAGNOSIS, ETC.

PARIS, January 24, 1897.

THE new and Draconian laws regulating the practice of medicine on French territory are making themselves felt much sooner than was anticipated. The statistics show that at the end of the scholastic year, 1894 to 1895, the number of students at the Faculty of Medicine of Paris was 5,239. At the end of the year 1895–1896 the number of the same students was 4,940, or in other words there had been a diminution of 299, which is considerable. This is evidently a first step toward disencumbering our medical school and studies, and augurs a better future for the medical profession throughout France—better not only regarding qualification but better also in the every-day practical and monetary sense. Two factors have contributed largely to bring about this notable diminution: first, the number of aspirants for the grade of *officier de santé* is steadily decreasing and will soon stop altogether, as the grade has been abolished by the new law, which allows only those to go on and take the degree who had been matriculated before the new law came into force; also those who matriculated after the law had been passed but before it became active, covering a period of a year or a little more. Second, the Faculty of Medicine of Paris no longer opens its door to foreign students, or only very exceptionally. Among the 4,940 student doctors, or *officiers de santé*, there are 3,976 Frenchmen and 964 foreigners—810 men and 154 women. This shows that the proportion of foreign students is still about 1 to 4 French, say 25 per 100. This year only 40 foreigners have been authorized to pursue their studies at the Faculty of Medicine of Paris—a very decided falling off. These students are divided as regards nationality as follows: 15 Russians, 9 Turks, 4 Roumanians, 2 English, and 2 Austrians. America, Germany, Holland, Belgium, Italy, Greece, Switzerland, and Africa have each only one authorized student. We say authorized in distinction from those foreign medical students who are unauthorized—that is, who follow certain public lectures and visit the hospitals, which I believe they are welcome to do without any special permission being granted or registration required. This year (that is, the last academic year), the Faculty of Medicine has received 594 new doctors, of whom 95 were foreigners. This is the medical balance sheet for 1896 and we may expect a smaller one each succeeding year, which will please the French profession at large: as, owing to overcrowding, it is not the doctors that are wanting, but the patients.

Regarding legislation in the different countries of Europe from a hygienic standpoint and as affecting women and children engaged in industry, Dr. Napias has just made a very valuable and interesting communication at the meeting of the Academy of Medicine held on January 12, 1897. It appears therefrom that the age of admission of children to industrial work of all kinds varies somewhat in the different countries. For instance, in Italy it is nine years—the youngest of all. In Switzerland and Austria fourteen is the age at which they are admitted to work in factories and industrial establishments generally. As regards the limit of age for protection, it is at its minimum in Italy, all protection ceasing in that country from twelve years old and upward for both sexes. This age limit, however, varies in other countries, and the mean in the larger number of States or countries is from sixteen to eighteen years. Nevertheless for girls it is raised to twenty-one years, and even more in some countries. Finally, the law in Switzerland and Austria regulates the duration of work as well for men and women as for boys. Dr. Napias shows us that the day of twelve hours for children and adolescents has become a rarity, and that it exists only in Belgium and to a very slight extent in Hungary.

The working classes in France certainly have no cause to complain that their interests, at least hygienically, are not carefully looked after. The Academy of Medicine has published its list of proposed prizes for the year 1899: they are twenty-seven in number, all being monetary and ranging in amounts from 600, 700, and 800 francs to 3,000, 5,000, and 6,800 francs. The works presented for the prizes, which are of course competitive, must be written in French or in Latin, and accompanied by a sealed envelope containing a device and indicating the name and address of the author. The works of foreigners are likewise admitted in competition for all the prizes except three. It is also announced that whoever shall make himself known, either directly or indirectly, will be excluded *ipso facto* from the competition. Furthermore, the printed matter, manuscripts, instruments, etc., submitted for examination to the Academy of Medicine, will not be returned to the authors or owners; only the recipients of prizes will be allowed the title of "laureate of the Academy of Medicine."

It is a well-known fact among practitioners, not only in France but also in the United States, that some patients cannot take quinine, even in the smallest doses, without its provoking ringing in the ears, deafness, sometimes vertigo, a sense of cerebral congestion, headache, and other symptoms of this order, in certain cases so accentuated that it is necessary to stop its exhibition altogether. Dr. Aubert guards against these inconveniences and, indeed, overcomes them entirely by atropine associated with the quinine in the following formula:

℞ Chlorhydrosulphate of quinine..... 0.40 cgm.
Sulphate of atropine..... ½ mgm.

This is for one dose and it is best taken in a wafer.

The fact that atropine thus attenuates or causes to disappear entirely the disagreeable symptoms often caused by the salts of quinine deserves to be brought to the notice of the profession at large and adds another to the list of drugs that atropine makes tolerable, for we already know that the nausea caused by hypodermic injections of morphine, and with stronger reason when morphine is taken by the mouth, is prevented or attenuated by the addition of a small quantity of atropine. Drs. Aubert and Petger have noticed the utility of belladonna as a means of making iodide of potassium more tolerable. It would seem then that belladonna is efficacious against quininism, and evidently succeeds better than other drugs suggested for that purpose, such as the bromide of potassium and ergotine, either alone or combined with opium.

At the last meeting of the Medical Society of the Hospitals, Dr. Moutard-Martin presented a patient who had entered the hospital with the diagnosis of aneurism of the aorta, and in whose case the radioscope showed conclusively a displacement of the right heart, probably caused by an old pleurisy.

WHAT'S IN A NAME?

To the Editor of the Medical Record.

Sir: It gave me great pleasure to read the letter of Dr. Gerster in the issue for January 23, 1897, of the Medical Record. I fully agree, as a matter of course, with Dr. Gerster that the word appendicitis, which is a most abominable one, should be placed on an *index verborum prohibitorum* to be created by us. The word for appendix vermiformis, which I find in my Greek book on anatomy, is σκωληκοειδὴς ἔκφυσις; which word the Greeks employ for appendicitis, if apophysitis or ekphysitis or scolecitis, I do not know. I have no Greek book on surgery. I shall write for such a book, however, in order to be able to give the term in living Greek of this not only, but of some other words in our surgical nomenclature, the composition of which seems to be rather arbitrary. Dr. A. Rose.

[The Greeks say φλεγμονὴ τῆς σκωληκοειδοῦς ἀποφύσεως, or σκωληκοειδῖτις, or, borrowing from the French, *appendicite*. Scolecoiditis might do, but appendicitis has probably come to stay. After all, the important question is not one of name (that which we call a rose by any other name would smell as sweet), but what to do with the pesky thing.—Ed.]

"MICROSCOPICAL POWER OF THE NORMAL EYE" AN ERROR.

To the Editor of the Medical Record.

Sir: In the Medical Record for January 23d is an article on "The Microscopical Power of the Normal Eye," by Dr. Roehrig, in which he describes two common phenomena which he mistook for a magnification of a hair. What he really saw was a doubling of the hair or object, and this method is one of the ways of proving the wave theory of light. And what he mistook for the air tube of the hair was the bright line made by the waves of light coming together after having passed around or by the hair. And the two dark lines he mistook for the sides of the hair were the two shadows of the hair, and not one. This can be shown better by not holding it before the eyes, but before a piece of white paper, using the same method, and is called a defraction ghost by microscopists, and is usually fully described in works on physics. Therefore, what he really did was to hold the object at such a distance from the pupil that both of the shadows could enter it. This phenomenon can also be illustrated by using a card with a narrow slit cut in it, in which case the centre will be dark instead of light, as is the case with solid objects, and of course in either case, if the objects are held far enough from the eye, it will readily be seen that it is two objects and not one enlarged object. Of course, when he used both eyes at once, then the objects was enlarged with a light centre. It was the effect of double vision, and is fully described in all works on physiology. It does not seem possible that he would have been deceived with both eyes, if he had not been first deceived by one. But it shows how easy it is for us to deceive ourselves even with things we are perfectly familiar with, if we find them when we are not looking for them.

R. C. Paine, M.D.

Bethel, Sullivan County, N. Y.

PRIVATE CHARITIES AND PUBLIC MONEY.

To the Editor of the Medical Record.

Sir: May I ask your kind indulgence to answer a few points contained in the reply of the president of the New York Post-Graduate Medical School and Hospital to my article that appeared in your columns on January 16th.

He says: "I beg to state that it is a mistake to call the New York Post-Graduate Medical School and Hospital a private institution unless various qualifications are made." It has received the charter which all educational institutions, as I understand it, have now to receive at the hands of the University of the State of New York, whether private or public: it has its separate board of directors; its autonomy is preserved; it is not connected with any institution of learning, either college or university; in fact, it was started as a private teaching body, and, so far as I have reason to believe, has never changed that character. I believe it would be regarded as a private institution by the generality of people, and no amount of denial or verbal juggling will alter that fact.

As regards the hospital attachment: the school began as a centre of teaching and was dependent for its clinical material upon the hospitals and other institutions with which the various members of its teaching body were connected: but it was early seen that this was not a good way of teaching, and, from small beginnings, the hospital arose to its present proportions. Had there been no school, there would have been no hospital. The hospital originated from the needs of the school as a teaching body and not as a charitable or benevolent institution, and therefore I do not regard it, and I do not think the majority of people would regard it, in the light of a charitable organization.

The president of this private corporation lays stress upon the fact that the "professors and instructors . . . have never received any dividends from the investment of their time and money," which I believe to be perfectly correct. He adds "that they have never supposed that they would get any." There I cannot

agree with him, as I remember very distinctly that in the beginning it was understood and intended that the fees derived by the various men from their teaching would go to them; but it was found impossible to do that, for not only did the school need everything that it could get from tuition fees, but more besides, and the teachers helped it along with contributions from their private purses. If he will look at the minutes of the early period of the school's life, I believe he will find that I am correct.

He goes on to say that the "Post-Graduate asked nothing from the State until we had invested much more than half a million of dollars in the plant, land, and buildings; until we had spent twelve years in unremitting labor," etc. His statement is rather misleading. The institution gets nothing from the State. It got from the legislature an amendment to a bill already existing, in which the board of estimate and apportionment was authorized in its discretion, etc. From his statement contained in the article published it would appear that the New York Post-Graduate Medical School and Hospital is a State institution, which it most certainly is not.

He says: "The bill granting this [appropriation] passed the legislature, was commented on in the public press, went to the mayor of the city of New York, received his approval, without which it could not have been a law, and was finally, after full consideration, signed by the governor. It is remarkable that the medical taxpayers, whom your correspondent desires to represent, did not take advantage of any of these opportunities to oppose the bill." I must disclaim any desire to represent the "medical taxpayers," but with regard to the great notoriety which the president of this private institution claims was made, if my memory holds good, there was very little said about it and it was not discussed publicly, certainly not in the medical profession, and I remember after its passage one of the members of the faculty of the Post-Graduate laughingly joked with me about the matter, stating that a march had been stolen and that they had got a grant of money which gave them a new lease of power. I can assure the president of this private institution that, had I known of it, I should have fought it tooth and nail, as I did last December.

It is a pity that a little more attention was not given to accuracy in the article, for the president says, in speaking of the action of the board of estimate and apportionment: "Even the two members who voted against us in the beginning, finally concurred in this view, [that is, that the institution should receive at least $20,000], for, as I understand the matter, no appropriation by the board of estimate is valid unless it be made unanimously." This is an error. A majority vote only is required, and if he had taken pains to consult the *City Record* of January 12, 1897, he would have seen the following statement:

"The comptroller moved to amend by allowing the sum of $25,000 for the purpose, which was adopted by the following vote: Affirmative, the mayor, comptroller, and president of the board of aldermen (3). Negative, the president of the department of taxes and assessments and the counsel to the corporation (2)." It was the mayor's vote that cost the city $10,000, and made this private institution so much the richer.

It is not necessary to fill up the columns of the MEDICAL RECORD in discussing the question as to whether State or city aid should be given to private institutions, nor whether there is an insufficient number of hospitals, dispensaries, etc., nor is it necessary to take the part of the MEDICAL RECORD in reply to the surprise expressed by the president of this private corporation "that your great journal should publish in a leading article that which seems to invite such attacks upon us as the one I have been criticising." The MEDICAL RECORD is amply able to take care of itself. It is certainly deserving of the thanks of the medical profession for calling attention to this form of abuse.

One point may perhaps be commented upon, and that is the objection which the president makes to the use of the word "plunder" in the last part of the article in the MEDICAL RECORD of January 16th, and he defines plunder as "money or valuables taken by force or by fraud from an enemy." He gives no authority, so I am unable to say from what dictionary he takes his definition; but in the Standard Dictionary under the word plunder is put "synonym: booty, pillage, prey, rapine, robbery, spoil, stolen goods, stolen property;" in the Encyclopædic Dictionary "as that which is plundered or taken by open force from another body; spoil, pillage, prey." The Century Dictionary gives as the meaning of the word plunder, "that which is taken from an enemy by force: pillage, prey, spoil, booty." Now I think there is very little doubt that the moneys which are given from the public purse for private uses may be fairly considered in the light of spoil. The money raised by taxation is money that is held in trust for the people for public purposes, and to my mind it is as wrong for these moneys to be diverted to assist private institutions as it would be for the trustee of an estate to use the money of his ward to support a foundling asylum or a home for destitute orphans.

I think, therefore, that the term "plunder" may be very properly used in this connection, notwithstanding that it seems to him such a harsh word.

The benevolent president of this private institution adds, possibly as a covert threat, that "I [he] think your correspondent will ultimately regret that he applied such a term to the aid received by us from the State." That sentence contains a very misleading statement. The aid is not from the State. It is from the city treasury.

As to the "well-dressed mendicants" which sticks in his crop, he says: "We did not become well dressed from dividends or salaries from our institution." *Qui s'excuse s'accuse.* Nobody has accused the gentlemen connected with this institution with diverting any of the money received by them for personal purposes. I am sorry that this gentleman should consider it necessary to bring this in.

But when you see a party of gentlemen, while presenting their claims for recognition as recipients of a public charity, clustering round the board which is to make the decision, and, while their fate is hanging in the balance, say in a low voice, "Make it twenty-five, make it twenty-five," I think it would excite in any one, as it did in me, a feeling of disgust, and I do not think that the term mendicants is one whit too strong for them.

It is possible, as the president of this private corporation says: "In spite of the views of your correspondent, I am happy in the belief that we have the confidence of the members of that profession [the medical profession] from Canada to Texas." Possibly, and perhaps this is so on the principle that "distance lends enchantment," etc., but I doubt if his institution enjoys the same "confidence" of the members of the profession in New York City.

F. R. STURGIS, M.D.

February 3, 1897.

Corns on the Soles.—A boy of fifteen years presented himself, with about twenty corns upon the foot soles, which rendered walking almost impossible. Hot bath of saturated solution of caustic potash, fuming nitric acid, followed by application of salicylated collodion.—*British Medical Journal.*

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending February 6, 1897:

	Cases.	Deaths.
Tuberculosis	161	136
Typhoid fever	7	2
Scarlet fever	147	7
Cerebro-spinal meningitis	1	1
Measles	169	5
Diphtheria	207	31
Laryngeal diphtheria (croup)	21	10
Chicken-pox	22	0

Why Medical Bills Should be Paid.—One occasionally comes across a layman who appreciates what the medical profession, as a whole, is doing for the public; but it is not often that we hear so much true sentiment uttered in our behalf as in a late sermon of the bishop of Norwich, England, as quoted by the *Medical Herald*. He is there reported as saying: "Nor can I, nor shall I, be silent about the wrongs to which scores of medical men are subject. I refer to the startling contrast there is between the inexorable demands which society makes on medical men, and the elasticity of the social conscience with respect to his remuneration. I have known cases where they are summoned at all hours and all seasons of the year. Their bills are presented with timidity, if not anxiety, and they are sometimes received with amazement, sometimes with indignation, and sometimes relegated to oblivion. Nor are cases unknown where the righteous demand for work done is met by calling in another practitioner; he, in turn, to suffer as his brother did before him. I cannot permit myself to imagine that I address any such wrong doer here to-day. But if I do, then, in my Master's name, I entreat you to remember that the medical men of this nation are the highest type of their class in the world; they are entrusted with the secrets of domestic life; they have all our liabilities of their order; they frequently die as martyrs to science, to suffering, to sympathy, to destitution. Believing this, my plea is that every unpaid medical bill be discharged generously, gratefully, cheerfully, and that, whatever account must be deferred in payment, the last to be deferred is the account of him who is the human agent who has brought us into the world, enables us to continue our work in life, and many a time lays down his own in endeavoring to baffle death."

The Treatment of Inevitable Abortion.—According to Gould, an "inevitable abortion is when the embryo or fœtus is dead, or when there is an extensive detachment or rupture of the ovum." The symptoms of this condition are dilatation of the cervix, uterine contractions, the loss of the angle between the lower and upper uterine segments, and uterine hemorrhage. Of the two classes of abortion, viz., criminal and accidental, the former, in this *fin de siècle* age, is the one most frequently met with. When the evidence of an attempt to terminate gestation is positive, even though hemorrhage may be slight and the degree of dilatation of the cervix insignificant, threatened criminal abortion should be considered as inevitable. The fame of the catheter and its use in this connection is world-wide, yet how many women fail to appreciate the pernicious results which may follow its use! How is it possible to determine whether or not septic matter has been introduced into the cavity of the uterus with the instrument, until certain symptoms are manifest? Is it not safer practice, therefore, to consider such cases as inevitable rather than to temporize? There is but one indication for treatment, and that is to empty the uterine cavity. This is best accomplished, after rapid dilatation of the cervical canal with the Goodell dilator, by means of the index finger. After removing as much of the products of conception as possible, the cavity should be thoroughly curetted with the sharp curette. Some advise the use of the vaginal tampon, but tamponage is procrastination and should be condemned; curettage, though radical, is the rational treatment. This procedure is particularly applicable in cases of the criminal variety, for the abortion will usually be incomplete; it is equally valuable in the accidental cases, for we cannot be positive that the abortion will be complete, as small pieces of the decidua vera sometimes remain attached to the uterine wall. These may be discharged with the lochial secretion, or, on the other hand, may remain and be the starting-point for a septic process. Taking it for granted, then, that abortion is seldom complete, is it not best to empty the uterus at once, when it seems inevitable, rather than to temporize, waiting, as did Micawber, for something to turn up? The curette answers every indication. After its thorough use the uterus contracts, pain ceases, and the hemorrhage is stopped, and the patient is placed in an ideal condition for convalescence. The danger arising from this procedure is remote. The operation should be performed, however, under the strictest observance of surgical asepsis, for upon the thoroughness of your technique depends your success. The anæsthetic may add an element of danger, consequently great care should be exercised in administering it to patients suffering from acute anæmia. The question of the employment of drainage after curettage is a mooted one, some claiming that by the use of gauze we prevent rather than favor drainage. This may be true if the uterus is packed tightly, but if a narrow strip of sterilized iodoform gauze is carried to the fundus drainage is not only facilitated, but by its stimulating action the uterus is kept in a state of tonic contraction. Its use also prevents the possibility of the agglutination of the two raw surfaces of the uterine canal, a condition which has been known to occur.—Dr. Carey Kennedy Fleming, *in Denver Medical Times*.

Lepra.—From the experience in Norway with isolation of lepers Dr. M. Joseph holds the contagiousness of the affection as proven. The degree of danger depends upon the social position of those concerned.—*Therap. Woch.*, No. 47.

Foreign Bodies are looked upon by Dr. Hummel as the media of infection in most instances of actinomycosis. Seeds and grain are usually the agents at fault.

The Parasite of Whooping-Cough.—M. Kurloff (*Vratch*, No. 3, 1896) remarks that Henke and Deichler have for the last ten years maintained that the cause of whooping-cough is a very active organism provided with cilia. He challenges this statement, and believes that the micro-organism of whooping-cough is not to be sought for among bacteria, but

among the protozoa. He has never failed to find active amœbæ with finely granular protoplasm and with spherical spores characterized by concentric lamination. He believes he has been able to follow the development of the spores into amœbæ. The facts he describes may all be observed in the fresh sputa of the patients, even without the employment of an Abbé's condenser.—*The Lancet.*

Infection with Leprosy.—Goldschmied has observed in Madeira the infection of a healthy child by a leprous nurse.

Street Noises.—London has its grievances as well as New York, but there steps are being taken by the city government to mitigate or suppress such street noises as constitute a public nuisance. Why can we not have the same?

Nervous Stability Considered from the Standpoint of Education and Training.—Dr. Jones (*Northwestern Lancet*, December 1, 1896) writes as follows on this subject: "There is unquestionably a growing and widespread tendency to degeneracy, anatomical as well as social. It invades the literature of the day to a nauseating degree. New writers are constantly pouring books upon the unsuspecting public that appeal to the emotional and animal nature. The characters, clothed in fine linen, are at heart perverts or defectives, and show the abnormal mind of the writer, who in private life is a leech, preying upon the credulity of readers, leading them in unhealthy paths of thought, appealing to wrong reason, and in the end dragging down respectability. The remedy for these ills is properly to train, direct, educate, and surround the growing brain, to the end that strength, force, observation, and reason may overcome degeneracy."

Test for Bile Salts.—It occasionally happens that the urine from icteric patients, although presenting the color and other appearances of containing normal bile pigment, does not respond to the tests of bilirubin. Instead of green, a red or even a blackish color may appear. In these cases the bilirubin has undergone some transformation, perhaps reduction to urobilin, and is incapable of being converted into biliverdin.—Dr. J. B. Nichols, *Medical News*, December 26, 1896.

How a Baby "Acquires."—A very interesting article with the above heading appeared in a recent number of *Nursery Guide*, and is quoted as follows: "At birth a child is simply 'organized suction.' He is a little bundle of animal appetites and propensities, with latent potentiality for good or bad. He is simply what he is by inheritance, as he has yet acquired nothing. He develops in body and mind according to natural laws. At first, hereditary tendencies predominate; then, finally, through environment and education acquired tendencies prevail, and life is thus made up of predisposition and acquisition. Predisposition, or hereditary tendency, determines greatly the nature, quality, and extent of all acquisitions—physical, mental, or moral. It is essential, therefore, that children should be well born, as well as properly trained. Training should precede birth."

A Large Hydrocele.—Dr. L. R. Markly, of Washington (*Medical Sentinel*, December, 1896), reports a case of hydrocele which he tapped, and from which he drew off twenty-two ounces of fluid. The patient was sixty years of age.

Antitoxin.—The following appears in an editorial (*Boston Medical and Surgical Journal*, December 17, 1896): "The strength of antitoxin is at present determined as follows: Diphtheria toxin, the germ-free filtrate of bouillon cultures of the diphtheria bacillus, is injected subcutaneously into a series of guinea-pigs of nearly uniform weight to determine accurately the smallest quantity of toxin which is fatal to the guinea-pig. When this has been determined, the toxin becomes the test toxin. A given quantity of serum to be standardized is mixed with ten times the minimum fatal dose of the test toxin and injected subcutaneously into guinea-pigs of nearly the same weight as those used in standardizing the toxin. If no local œdema or infiltration appears—if, in other words, the guinea-pig is completely protected, the quantity of serum used contains one-tenth of an antitoxic unit."

Cerebral Syphilis.—It may safely be said that, with the exception of embolism, the large proportion of the cases of apoplexy occurring between the ages of twenty and forty years are due to syphilitic disease of the cerebral blood-vessels.

How to Eat.—The *Boston Medical and Surgical Journal*, No. 18, 1896, says that Charaka Samhita, the great Indian physician, was about right when he said: "One should take one's food in a place that is agreeable. The food one takes should, again, consist of dishes every one of which is agreeable. One should eat not with haste, or taking up a long time, or talking or laughing the while. While eating, one should eat with attention concentrated thereon. Lastly, one should eat after a proper survey of one's self."

The Penalty for Non-Vaccination.—Gloucester, England, was the scene of the life and work of Jenner, and it seems strange to report that this same town has suffered an epidemic of small-pox, the like of which has not been experienced by any other town in England for years. A detailed account of this epidemic, published in *The Times*, last August, furnishes the following statement of facts: Between 1886 and 1894 the number of public vaccinations had fallen from 1,095 to 34, and in ten years the total was only 2,378, though in that period 15,682 children had been born in Gloucester and only 3,176 had died. The epidemic began with a case of small-pox in an unvaccinated child which was concealed and treated as measles. The end of the epidemic was certainly not due to effective isolation nor to the exhaustion of the virulence of the infection. When the city began to be boycotted the citizens appealed to the city council; the council appealed to the doctors; and the doctors replied that isolation, vaccination, and re-vaccination were the necessity of the time. Finally, the board of guardians instructed the vaccination officers to carry out the law. More than 36,000 vaccinations were effected. The epidemic was brought under control in May, and by the end of July it had been stamped out. The epidemic had attacked 2,036 persons (the population being about 40,000), of whom 443 died. The guardians are now prosecuting vaccination defaulters with energy as great as their previous indifference.

Books Received.

While the Medical Record *is pleased to receive all new publications which may be sent to it, and an acknowledgment will be promptly made of their receipt under this heading, it must be with the distinct understanding that its necessities are such that it cannot be considered under obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

UNILATERAL AND COMPLETE EXCLUSION OF THE INTESTINE FOR FÆCAL FISTULA.

BY F. KAMMERER, M.D.,

SURGEON TO THE ST. FRANCIS AND GERMAN HOSPITALS.

THE difficulties which the surgeon encounters in the treatment of fæcal fistula in the cæcal region, of whatever origin, are well known. When this region has been the seat of prolonged inflammation and many adhesions have formed between the intestines, resections of the cæcum, followed by suture of the divided ends of the bowel, have generally proven an unreliable method for the closure of the opening in the intestinal wall. Usually, primary union is not obtained in these cases, and a fæcal fistula again becomes established.

The difficulties in the way of the union of the divided ends in uncomplicated cases, such as inequality of the lumen of the ileum and of the colon, the absence of a peritoneal investment at the broad mesenteric border of the colon, the shortness of the mesocolon, preventing easy approximation of the divided ends—all these are not more readily surmounted when we are operating within dense adhesions of the intestines, and, consequently, dealing with a much altered visceral peritoneum. The many failures which have attended resections in the cæcal region for the cure of fistula in former years have gradually convinced surgeons that relief from these conditions must be sought by operations upon normal parts of the intestinal tract, away from the seat of intestinal adhesions. Naturally enough, intestinal anastomosis by lateral apposition of two loops of normal intestine, lying as near as possible to the fistula, was the first alternative that suggested itself to surgeons. It was Maisonneuve[1] who first conceived the idea of lateral anastomosis and carried it out practically on animals and in two cases of hernia with varying success. Billroth revived the operation in 1881; his patient died of peritonitis. Then his assistant, Von Hacker, took up the operation some years later, and, while he performed it four times for indications other than fistula, he nevertheless recommended it for the latter condition when firm and extended adhesions were anticipated. It should further be stated here that Von Hacker[2] practised narrowing of the lumen of the intestine on the proximal side of the affected portion, between it and the anastomosis, by suturing the intestine in longitudinal folds, his idea being to prevent the approach of intestinal contents to the seat of disease. Outside of this recommendation of Von Hacker, I have not been able to find any case of fæcal fistula treated successfully by lateral anastomosis alone. We may speak of lateral anastomosis as an incomplete exclusion of a part of the intestinal tract from the fæcal circulation.

Theoretical reasoning, perhaps to a greater extent than failure in practice, led to the idea of complete exclusion. This operation has been occasionally resorted to in late years for ailments of the cæcum and adjacent bowels. The term is applied to that procedure by which a certain portion of the intestinal tract, while remaining in connection with its mesentery, is entirely withdrawn from the fæcal circulation, its divided ends being either both closed by sutures or implanted one or both into the abdominal walls, to allow an exit for previously accumulated fæcal matter or later secretions from the intestinal walls. Whether or not the excluded portion be hermetically sealed is immaterial. All these varieties should be included under the heading of "total or bilateral exclusion."

A great amount of discussion has been carried on as to the propriety of absolutely shutting off portions of intestines. Salzer,[3] who first conceived the idea of total exclusion in preference to lateral anastomosis, operated on animals only, never having had occasion to verify the conclusions he came to on the living human being. These have, however, been accepted by many surgeons, and centre in the proposition that hermetical closure of a portion of intestine is, to say the least, a hazardous procedure. In later experiments, when greater care was taken in the preparation of his animals before operation, Salzer found that total exclusion without drainage of the excluded portion, was not necessarily a fatal operation. The subjects of such experimentation survived the operation for an indefinite period, and did not succumb to peritonitis as in former experiments, the result of decomposition of imprisoned material, necrosis of the intestinal walls, and rupture and extravasation into the peritoneal cavity. Other investigators have had similar results. If thorough disinfection of the excluded intestine has been accomplished and the gut itself is in a normal condition, the secretion from its walls will be very slight. But if the walls are the seat of pathological changes and disinfection has been omitted, especially in the small intestine, great distention of the loop with gaseous and fluid material, the latter resembling liquid fæces, will follow. The large and small intestines differ greatly in this respect. In the former, the secreting power of its mucous membrane is very slight, and absorption is rather the rule. In the small intestine, on the contrary, the secreting glands are very active. It is on this account, no doubt, that the few who have practised total exclusion with hermetical closure have operated on the large intestine. Such cases have been reported by Baracz[2] and Obalinski[3] with a favorable issue, both as regards immediate result and the further course of the cases. The only case of total exclusion of small intestine, which I have found, is reported by Parkhill,[4] of which I will take occasion to speak later on. His patient was entirely well one and a half months after operation, not a very long period it is true.

I have operated on two patients for fæcal fistula following appendicitis. In one case unilateral exclusion resulted in complete cure; in the other it had to

be supplemented by total exclusion. The cases are the following:

Case I.—W. R. J——, aged eighteen years, was admitted to the St. Francis Hospital on May 26, 1895, to the service of Dr. Shrady, suffering from acute appendicitis. He had never been ill before. On May 27th Dr. Shrady operated upon the large abscess, the contents of which showed distinct contamination with fæcal matter. The gangrenous appendix which formed part of the wall of the abscess could not be removed with safety. The abscess cavity was packed and drained with iodoform gauze. On June 8th the fæcal discharge from the wound became very pronounced, and from this day on all fæcal matter passed through the wound and none by the rectum. The wound surfaces gradually contracted but showed no tendency to close, a large fistula still existing on August 21st, from which defecation occurred. On this day the patient was put under ether, and after thorough disin-

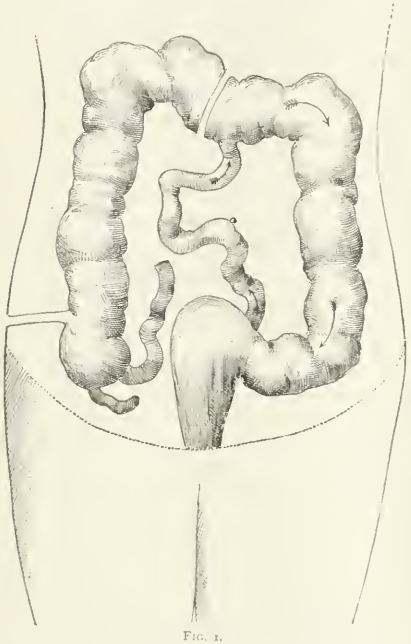

Fig. 1.

fection the fistulous opening was temporarily closed by several sutures passing through the abdominal walls, with avoidance of the peritoneum. The abdomen was now opened in the median line from a point two inches above the umbilicus to the symphysis pubis. It then became apparent that the adhesions of the intestine were not confined to the right iliac region, but that the entire omentum was bound to the intestines at various points. It required considerable time to separate the adherent omentum, and to recognize the point at which the ileum joins the cæcum. A point about eight inches from the cæcum was chosen for the division of the ileum, and after closure of the distal end the proximal end was implanted by a Murphy button into the lower border of the transverse colon, which was very pale and much contracted, looking like a loop of small intestine. Some difficulty was also experienced in bringing together the proximal end of the divided ileum and the transverse colon, again owing to the adhesions. The approximation was so perfect that no supplementary sutures were deemed necessary, and the abdomen was closed. The operation had lasted slightly over two hours (see Fig. 1). The further course of the case was uneventful. The button passed on the eighth day, and no fæcal matter has escaped from the fistula since the day of operation. There was no sign, however, of a spontaneous closure of the fistulous opening. It remained patent and occasionally discharged a little clear gelatinous fluid. Therefore on September 22d an attempt was made to suture it, which was in the main successful, but at the end of a fortnight a very small sinus, just admitting a probe, again appeared, discharging the same mucus as before. This finally closed by granulations by the end of October. The patient is at present in excellent health, and has gained considerably in weight. During the first week or two after the escape of the button, he complained several times of colicky pains on the right side, which were never very severe and have never since reappeared. To my knowledge this is the first case of successful unilateral exclusion of the normal ileum and colon recorded.

Case II.—G. T., aged forty-eight years, was operated on for appendicitis with abscess, by a leading surgeon of this city, three times from February to October, 1895. After the last operation a fæcal fistula developed at the site of the wound, through which at present (December, 1895) almost all fæcal matter is discharged, a very small quantity occasionally passing through the anus. When admitted to the hospital the patient was in good general condition. In the right iliac region a granulating surface, four inches in length, is seen, from which an opening, admitting one finger, passes into the large intestine along a sinus about two inches long. At the lower angle of the incision there is a second passage, just admitting a probe, running in an upward direction, and meeting the fistulous sinus at its junction with the bowel. There is a constant discharge of fæces through these openings.

On February 8, 1896, an attempt was made to close the opening in the large intestine by a double row of sutures, after incising the bridge of soft tissues between the two fistulous tracts, and thorough dissection and scraping of the chronic abscess cavity surrounding the fistula. Although the ascending colon was separated from its surroundings, so that easy approximation of its edges was possible, the attempt was not successful, and the fistula reopened after the lapse of a week, discharging in the same manner as before operation. Owing to the dense adhesions which I encountered, I decided that intestinal anastomosis of the nearest available non-adherent portions of the small and large intestines was the proper course to follow.

On opening the abdomen on March 12th, the intestines in the right iliac region presented a mass of firm adherent viscera, from which, however, the lower end of the ileum was isolated and recognized at its junction with the large intestine. After shutting off the former with clamps, it was divided transversely at a point about six inches from the ileo-cæcal valve. Its distal end was now closed by a double row of sutures, and after division of its mesentery, the proximal end of the small intestine could be readily brought in contact with the transverse colon at about its middle portion, this being the nearest point available for the purpose, as the ascending colon was almost entirely enveloped in adhesions. An incision was made into the lower border of the colon at the point indicated, and the proximal end of the ileum again implanted by means of a Murphy button, supplemented by a row of Lembert sutures. The abdomen was closed and the patient put under the influence of opium. He made an excellent recovery, the button passing away on the tenth day. From this day on, the patient had daily evacuations of the bowels, being assisted by injections into the rectum. During the

first months following implantation, a large amount of fæcal matter continued to issue from the original fistula, but this discharge had almost entirely ceased when I saw the patient in October, after an intermission of half a year. Only a small amount of fæcal matter occasionally came away from the fistula, and the patient had one or two good movements of his bowels daily by the natural way. At the site of the original fistula, a large opening in the gut still existed, from which the intestinal mucous membrane protruded when the patient made violent exertions of his abdominal muscles.

On November 21st, the patient was anæsthetized for the closure of this fistula. I did not anticipate much difficulty in accomplishing this, as the condition of the parts was now much better than when I first made the attempt, inasmuch as the sinuses had closed and also the various abscess cavities around the fistula had become obliterated. The old difficulty, however, presented itself. After the intestinal loop had been separated from its adhesions for a long distance, the infiltration of the walls of the intestines was so great that no approximation of the resected edges was possible—not, at least, to such an extent that a double row of sutures could have been applied. To effect this, the ascending colon had to be liberated from its adhesions almost to the hepatic flexure, and the general peritoneal cavity opened. The intestine itself was much collapsed, its walls were very thin, and it was only recognized as the ascending colon by the longitudinal muscular fibres in its wall. In the direction of the ileum the large intestine was so firmly adherent that it was impossible to isolate it farther than about two inches from the fistula. It was now seen that the latter was in reality an almost complete transverse section of the colon. On introducing my finger into the bowel in the direction of the ileo-cæcal valve, the latter was found filled with hard fæcal concretions, although the patient had been carefully prepared for operation and his bowels thoroughly emptied. After resection of the ends of intestines a double row of sutures was applied, and the bowels were replaced within the abdominal cavity, surrounded by a small tampon. The abdominal incision was partially closed with silkworm sutures. The result of all this was that on the fifth day fæcal matter again appeared on the dressings, and in the course of a few weeks a fæcal fistula, admitting the tip of my finger, was again established, which discharged a considerable amount of fæcal matter.

On December 17th, the abdomen was again opened in the median line for several inches, to both sides of the umbilicus. A few adhesions of the omentum were found and easily separated, when the seat of the implantation done nine months ago was disclosed. At the point where the ileum was united to the colon there were no adhesions save a few strands running to the omentum. The anastomosis was perfect; there seemed to be no contraction at the line of union, nor was any cicatricial induration to be discovered on palpation. There was evidently no narrowing of the lumen at all. The first half of the transverse colon was brought outside the abdominal incision by the separation of a few further adhesions. After passing two pieces of iodoform gauze through the transverse mesocolon and tying them at a distance from each other of about two inches, the colon itself was divided transversely, and both its ends were closed by three rows of silk sutures: the gauze was removed, the bowel returned to the abdominal cavity and the abdomen closed, no tampon being introduced (see Fig. 2). This time also the patient did well. He was kept under opium for a week. During the first weeks small particles of fæcal matter escaped from the fistula. At the end of a week his bowels were first moved by small enemata, repeated at frequent intervals, and then by cathartics. The fistulous opening discharges a small amount of mucus, and an attempt to close it is not, I think, at the present indicated, but later on may become necessary as a matter of convenience for the patient.

I confess to having felt some disappointment at not being able to close the fistula after three prolonged operations, more especially after the very gratifying result in the first case which I have reported, in which implantation of the ileum into the transverse colon was immediately followed by a cessation of the discharge of fæces from the fistula. Two other cases which I have been able to find, in which a similar procedure was adopted, are reported by Koerte[1] and Parkhill.[2] In many points Koerte's case differed from the two I have reported. It was originally one of tuberculous degeneration of the cæcum, in which at a previous operation the ascending colon, the cæcum, and a small piece of the adjoining ileum had

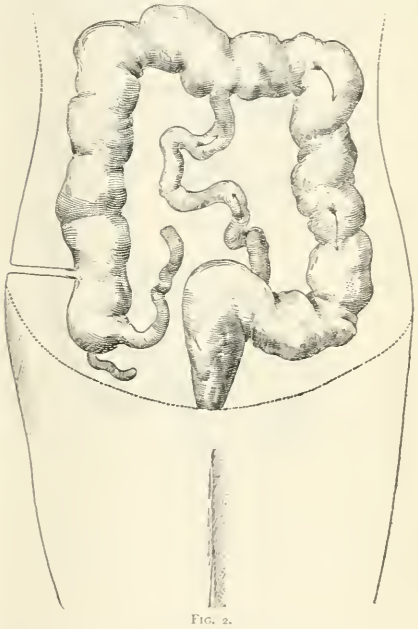

Fig. 2.

been resected, and the ends of the intestines had been implanted side by side into the abdominal wall. Application of Dupuytren's enterotome and various plastic operations were all of no avail in Koerte's case. The author then resected an additional twenty-one centimetres of colon at the site of the artificial anus, and sutured the open end. A loop of ileum was then attached to the colon about an inch from its closed end. The wound was tamponed, but on the fourth day after operation fæcal matter again appeared in the dressings, the sutures in the colon having given way. That this would have been the case, even if primary union of the colon had occurred, seems more than probable, as the divided end of the ileum was left open in the wound. Koerte, in his sixth operation on the same patient, divided the ileum, closed the distal end leading to the anastomosis and farther on to the fistula, and implanted the proximal end into the lowest portion of the descending colon. Some of the intestinal contents found their way in an antiperistaltic di-

[1] Koerte: Archiv für klin. Chirurgie, vol. xlviii., p. 717.
[2] Parkhill, l. c.

rection to the original fistula by way of the colon. In the seventh operation the colon was divided and both ends were hermetically closed by sutures, completely shutting off the fistula from the fæcal circulation. And, lastly, the entire excluded portion was successfully removed in an eighth operation, necessitated by an abundant discharge of mucus from the original fistula. I have tried to illustrate the operations in Koerte's case by the accompanying figure (Fig. 3). Parkhill's case resembles mine closely. He operated for fæcal fistula, also following a previous operation for appendicitis. After opening the abdomen he divided the ileum about three-quarters of an inch from the ileo-cæcal valve, closed the distal end, implanting the proximal end into the beginning of the hepatic flexure of the colon by means of a Murphy button. About three months after this operation the fistula had contracted to about two-thirds of its original size, and there was still some regurgitation of fæcal matter. Parkhill now resected the cæcum, closing the ascending colon near the site of his previous implantation, but found that the opening made by the Murphy button had contracted so much that he could barely introduce

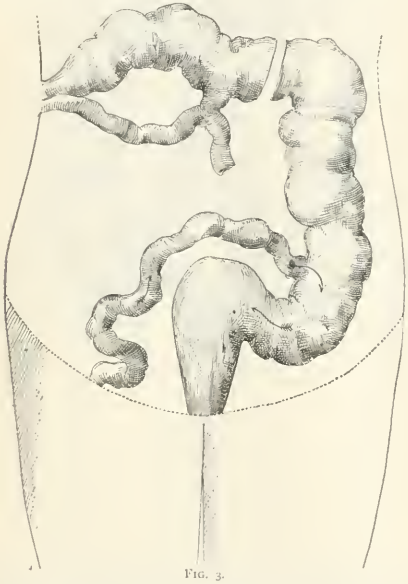

Fig. 3.

his index into the lumen of the ileum. He also introduced his index in the opposite direction, through the valve, but here "it was impossible to reach the end of the segment," showing evidently that the ileum had not been divided at the previous operation three-quarters of an inch from the valve. The ileum was closed after the cæcum had been removed, and the author leaves it an open question how much of the small intestine he had totally excluded from the fæcal circulation. His patient made an excellent recovery, and one and a half months later was entirely well, as I have previously stated.

Lateral anastomosis does not seem a rational procedure for the cure of fæcal fistula, although its efficacy in cases of inoperable neoplasms is sufficiently established, and needs no repetition here. There is no reason why the contents of the intestines should not further pass into the small intestine beyond the anastomosis, in the direction of the peristaltic wave, when there exists a point of exit for them in the fistula itself. In implantation of the ileum into the colon, with closure of the distal end of the ileum, the case is different. Here the intestinal contents will be forced to travel in a direction opposite to the normal peristaltic action, in order to appear at the fistula. That this does occur, at least to some extent, is proven by clinical observation in Koerte's and Parkhill's cases, and in one of my own. Experimental work seems to point in a similar direction. Haken[1] and Senn[2] have both done unilateral exclusion on animals, by dividing the ileum and implanting the proximal end into the colon, after closure of the distal end. Haken experimented on young pigs in pre-antiseptic times, and was successful in one such operation. He found at the autopsy, sixty-six days later, that the colon, cæcum, and small intestine, which had been excluded from the fæcal circulation on the proximal side, were very much contracted and practically empty, containing only a small quantity of intestinal mucus. Senn, in his extended experimental study, arrives at similar conclusions. In most of the records of his autopsies he mentions that occasionally excluded portions of bowel, both in operations of implantation and of lateral apposition after artificial stricture, are contracted and empty. Neither of the two authors alluded to any stasis of intestinal contents with distention or ulceration of the bowel in their experiments of unilateral exclusion; on the contrary, the intestine at the post-mortem examination was generally pale and atrophic.

Another surgeon, Reichel,[3] while criticising the successful cases of total exclusion of Baracz and Obalinski, has suggested the propriety of ileo-colostomy by implantation for the cure of fæcal fistula in the cæcal region, but he has never had occasion to perform the operation on the living human being.

I have reviewed the available experimental and clinical data at some length, as it seems remarkable that unilateral exclusion, with implantation of the ileum into the transverse colon, should not have been more frequently resorted to for the cure of fæcal fistula in the cæcum. Theoretically, it would seem to be the operation which would suggest itself in such cases. No objection to it can be made, I think, on the ground of stagnation of fæcal matter in the unilaterally excluded portion of ileum, the ascending colon, and transverse colon, for experiments and clinical observations make it more than probable that the intestines will suffer no harm from the presence of fæcal material, if an outlet (either a fistula or an open communication on one side of the excluded loop) is provided. Another consideration, which would be apt to prejudice in favor of unilateral exclusions, is the condition of the excluded portion some time after operation. It matters little, apparently, how unilateral exclusion is brought about. If we are dealing with a stricture, malignant or benign, or if a stricture be artificially produced, as in experiments, and if lateral anastomosis be done for its relief, assuming that the stricture is impermeable, there will result from this operation two unilaterally excluded portions of gut. The one leading to the stricture will generally be empty, although it has occasionally been found distended, more especially when the anastomotic opening has not been sufficiently large. The one leading from it will always be quite empty. It is with this latter portion that we are interested in the consideration of unilateral exclusion for fistula, and all experience, as I have just stated, goes to show that it will atrophy if its only outlet is at the seat of the anastomosis. All this is equally true of implantation. In forming an estimate of the value of unilateral exclusion, the next question presenting itself is: Does the excluded por-

[1] Haken, F. A.: "Allgemeine Bemerkungen zu den Hernien," Dissertation, Dorpat, 1861, pp. 95 and 99.
[2] Senn, N.: Annals of Surgery, vol. vii., p. 269.
[3] Reichel: Centralblatt für Chirurgie, 1895, p. 40.

tion undergo atrophy, and will the fæcal accumulation be avoided as well in cases of fistula—in other words, in those instances in which a second opening exists in the excluded portion? It is evident that the intestinal contents are more likely to enter the latter, if they can again leave it by another opening. I know of no experimental work to determine this point, but clinical observation seems to be in its favor. In three of the four cases in which unilateral exclusion by implantation was practised for fæcal fistula, fæcal matter continued to pass by the latter for some time, until further operations were done. Two of the cases (Koerte and Parkhill) were under observation a very short time only. In one of them the implantation was done on May 13th. On May 26th some fæces again appeared at the fistula. On June 3d the abdomen was reopened, and the transverse colon divided before the seat of implantation. In the other case, "the patient was readmitted at the end of a month, begging for a second operation. The fistula had contracted to about two-thirds of its original size, and there was still some regurgitation of fæcal matter." In the first of my two cases the effect of unilateral exclusion was a very marked one. Whereas, before the operation, all fæcal matter had escaped by way of the fistula, most of it now passed by the natural route. The same was the case in Koerte's patient. From Parkhill's statement of contraction of the fistula and still some regurgitation of fæcal matter, we must conclude, I think, that the condition of his patient was also very favorably affected by the operation. In my first case the result was a perfect one. No fæcal matter escaped from the fistula after unilateral exclusion by implantation was done. The result was so striking in this respect that the presence of a stricture between the fistula and the seat of implantation suggested itself to me, though the history of the case, both before and after the first operation, does not in the least warrant this assumption. I think we are, therefore, justified in concluding that the unilateral exclusion of a part of the ileum and the ascending colon, and part of the transverse colon, for fæcal fistula in the cæcal region, will at least result in determining the exit of by far the greater part of the intestinal contents by the natural way. Further, we are justified in assuming that this operation will be followed by atrophy of the excluded portion in a very short time, even if some fæcal matter still passes by the fistula. This was very apparent in my second case at the subsequent operation, performed some nine months after implantation, when the ascending colon was so much contracted that I at first took it to be the small intestine. And, lastly, one of my own cases has shown that, in probably very exceptional instances, unilateral exclusion is followed by complete cessation of the flow of fæcal matter from the fistula, and that a small plastic operation may permanently seal the abnormal opening.

It must be allowed that, once abdominal section and one of the methods of intestinal anastomosis are determined upon for fæcal fistula, the most radical and efficacious procedure is implantation of the ileum into the transverse colon, and total exclusion, after division of the latter, in one sitting. Then, of course, and then alone, we may feel sure that no more fæcal matter can pass by the fistula. There are, however, certain disadvantages connected with this plan. The division of the transverse colon and the suturing of its ends considerably prolong the operation of implantation, which is in itself occasionally a lengthy one, and adds an element of danger. Besides, we then have a totally excluded portion of intestine, which very often continues to secrete and discharge through the artificial opening a large quantity of matter. This, though not fæcal in character after a lapse of time, may still be the source of great annoyance to the patient, and has in some instances necessitated the removal of the entire excluded portion—a formidable operation when the latter includes the ileum, the ascending colon, and part of the transverse colon.

Such considerations should prompt us, I think, to attempt closure of a fistula in the cæcum, in the first instance, by implantation of the ileum into the colon (unilateral exclusion). If in the course of some months atrophy of the excluded portion should follow, a relatively insignificant plastic operation may be sufficient to close the fistula. Failing in this, we may at a later stage divide the colon on the proximal side of the implantation, and close both ends. My own experience seems to show that there will be little difficulty in finding the bowel in question, very few adhesions forming when a Murphy button has been used, undoubtedly the ideal method of union in end-to-side anastomosis of the ileum and the colon. If our efforts to close the fistula after unilateral exclusion by implantation have been unsuccessful, we might try to liberate the loop of intestine at the site of the fistula, and after transverse section close the distal end, leaving the proximal end open in the wound. I question whether this operation would be preferable to division of the transverse colon on the proximal side of the implantation, as previously suggested and practised in my second case, in which I was influenced by the many operative procedures which had been undertaken at the seat of the fistula, and which I reasoned had so altered the peritoneal surfaces that successful suturing would be a matter of some doubt. But if no attempts at repair have been previously made, I should be inclined to believe that the operation would be in a number of cases successful. Two advantages would accrue from this method. The patient would not be subjected to another laparotomy, and if later on the secretion from the fistula became very troublesome, a smaller piece of intestine would have to be removed to effect a permanent cure.

After implantation of the ileum into the transverse colon, we should make an immediate attempt to close the fistula at the same sitting. I have been very much annoyed in the later operation in my second case by the presence of fæcal matter in the unilaterally excluded portion of intestine, which of course could not be removed during the usual preparation of the patient for operation. It was very difficult to dislodge it after total exclusion was finally done. It seems, therefore, that we should try in the first instance after implantation, when we have still been able to effect evacuation of the contents from the entire intestinal tract, to close the fistula. If we fail in this, another attempt is indicated at the site of the fistula, as I have already stated, before total exclusion is practised.

In recommending unilateral exclusion in cases of fæcal fistula, I am well aware that it should not be resorted to in cases of malignant inoperable tumors of the cæcum or stenosis from other causes. For such cases intestinal anastomosis by lateral approximation or total exclusion, with implantation of both ends of the excluded loop into the abdominal walls, should be the operative measures applied, more especially when clinical symptoms point to ulceration and discharge into the lumen of the bowel. In such cases the risk of accumulation near an occluded end would be great. Of the two, lateral approximation, on account of its relative simplicity, should be the operation of choice. The argument in favor of total exclusion, with implantation of both ends into the abdominal wall, for the purpose of topical medication, in cases of intestinal tumors is, to my mind, of questionable value. If no ulceration is present, I think it would be better surgery simply to deflect the intestinal current from the seat of disease by lateral anastomosis than further to indulge in medical applications to the surface of the

growth. As for the prevention of further irritation by the passage of fæcal matter over the surface of the tumor, it will follow the establishing of a large lateral anastomosis, to all intents and purposes, as experiments with artificial constriction of the bowel have abundantly proven (Senn).[1]

When extensive adhesions are present, implantation will occasionally be rendered more difficult by a failure of the surgeon to recognize the direction of the small intestine. It is evident that we must be sure of implanting the proximal end of the divided ileum, or a very pronounced and undesirable condition will shortly manifest itself. In my first case for the recognition of this portion of the small intestine much dissection was necessary, and I can readily believe that with still firmer adhesions its identification may become wellnigh impossible. Prolonged efforts are surely indicated to find a loop of intestine near the ileo-cæcal junction, so that we may not only determine the direction of the fæcal stream but also prevent the exclusion of too long a piece of small intestine. If the adhesions are so firm that this is found absolutely impossible, then the only course remaining is to do an ileo-colostomy by lateral approximation, using the lowest coil of small intestine available.

The middle of the transverse colon seems to me for several reasons the best situation for implantation in the cases under consideration. It is most readily approximated to the divided end of the ileum, the ascending colon being generally so thoroughly enveloped in adhesions that it cannot be utilized for this purpose. At the same time, the greater portion of the colon being still in activity, sufficient absorption of fluids will continue to prevent the passage of liquid stools, which might occur if implantation were done low in the descending colon—an otherwise favorable position, in view of its great distance from the fistula.

A REPORT OF A PLASTIC OPERATION FOR RESTORING THE LOWER LIP.[2]

By CHARLES N. DOWD, M.D.,

ATTENDING SURGEON TO THE NEW YORK CANCER HOSPITAL.

THE patient shows the result of an operation done one year ago for epithelioma of the lower lip. There had been a sore on the lip for four years, and the growth had been advancing rapidly for a year. Not only was the lower lip involved, as is shown in the photograph, but there was extensive cancerous disease in the submaxillary spaces.

The operation was based on the method of Malgaigne, but the changes in surgical procedure since Malgaigne's time have led to a radical modification of his operation. His incisions are shown in the accompanying illustration (Fig. 3).

There are two main objections to this location of the lower incisions:

1. They do not expose the submaxillary spaces, in which diseased lymph nodes so often exist.

2. Unnecessary deformity is caused by the prominent position of the scars and the stretching of the narrow flaps.

These objections are obviated by carrying the lower incisions beneath the body of the jaw. They should extend from the tip of the chin nearly back to the angle of the jaw (see Fig. 4). Through these incisions the submaxillary spaces can be thoroughly cleared out. From this patient enough was taken from them to half fill a tumbler. In addition to a large number of carcinomatous lymph nodes, the submaxillary salivary glands were removed. I think the salivary glands need not be removed in all cases, as they are seldom cancerous, but in this instance they were

FIG. 1.—Patient Before Operation.

closely adherent to the cancerous lymph nodes and their removal seemed advisable. I have removed them from six or seven patients, and their absence occasions no perceptible derangement of the salivary apparatus.

The removal of the primary growth itself should be accomplished by incisions one-half to three-fourths of an inch from its margin. The entire lower lip and a small portion of the adjoining cheek were removed from this patient. The incisions may usually converge below, as is shown in Fig. 4. A good cosmetic

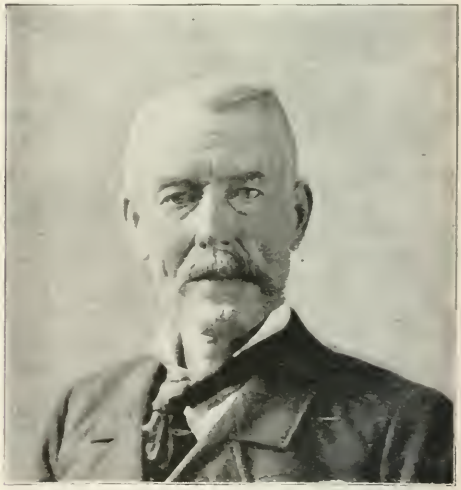

FIG. 2.—Patient One Year After Operation.

effect is promoted by leaving as much tissue as possible on the prominence of the chin; redundant tissue may be trimmed off if necessary when the stitches are taken.

The horizontal incisions from the angles of the mouth should be marked with the point of the knife

[1] Senn, M.: Annals of Surgery, vol. vii., p. 261 et seq.

[2] Patient presented before the surgical section of the New York Academy of Medicine, December 7, 1896.

before cutting, to insure symmetry. They should be carried backward two inches, or as far as is necessary to allow the approximation of the flaps. These incisions are carried down to the mucous membrane, but that is divided one-third inch higher than the skin, so that it may be laid over the edge of the newly formed lip and stitched to the skin without tension. A good vermilion border is thus formed. The excess

FIG 3.—Incisions for Malgaigne's Operation. From "Manuel de Medecine Opératoire," by Dr. J. F. Malgaigne. 9th Edition, par Léon Le Fort.

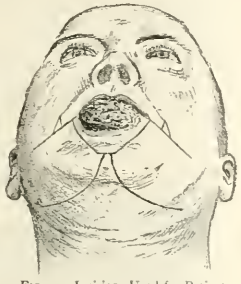

FIG. 4.—Incisions Used for Patient here Reported.

of tissue which is apparent in the cheeks above the incisions after the approximation of the flaps is remedied by the removal of wedges of skin, which are usually best taken so that the cicatrix will be in the line of the labio-nasal folds.

In liberating the flaps so as to allow their approximation, it may be necessary to divide at the mental foramen the mental branch of the inferior dental nerve. This need not be feared, as the branches of the facial nerve supply the power of motion to the newly formed lower lip, and the diminution in sensation is not troublesome. The divided nerve fibres apparently unite after a few weeks

The facial arteries and veins are usually severed in the submaxillary spaces, but the flaps are well nourished without them.

For sutures, silkworm gut may be used where there is tension—fine catgut for the mucous membranes within the mouth, and fine silk for the others.

The wound should be dressed lightly; a heavy dressing keeps it bathed in the discharges from the mouth. I have had the best results from a collodion film above, and below the chin a light gauze dressing, which is frequently changed.

For two or three days before the operation a mouth wash of equal parts of peroxide of hydrogen and water should be used every three or four hours; and after the operation the mouth should be syringed with a similar solution at the same intervals.

The patient should be able to drink fluid through a tube after the first twenty-four hours.

In this patient the wound was well healed in a week and the stitches were removed, four days later he was able to leave the hospital in the evening, and was shown at a meeting of the West End Medical Society. Two weeks after the operation he left the hospital, and soon afterward went to work. At the present time one might hold a conversation with him without noticing a deformity. The lip is of normal size, freely movable, and under good control. It has a good border of mucous membrane and a good lining of the same membrane, which extends downward below the base of the gum in the usual way, leaving abundant room between the lip and the gum. For eating, speaking, and retaining saliva, the lip is normal.

A lip which is formed from the cheeks in this way has a good lining and border of mucous membrane from the beginning, and does not show a tendency to cicatricial contraction; it also contains fibres of the orbicular muscle of the mouth. These advantages do not exist in lips which are formed by sliding up tissue from the chin.

The prospect for a permanent cure in this patient is good, as most of the recurrences appear within the first year.

I wish to urge the doing of this complete operation more generally, or of such a modification of it as permits the thorough clearing out of the submaxillary spaces. Patients are sent to the New York Cancer Hospital every year from whom labial cancers have been removed and in whom the growths have continued, first in the submaxillary spaces, then in the jaw, base of tongue, and adjacent structures, until cure is impossible.

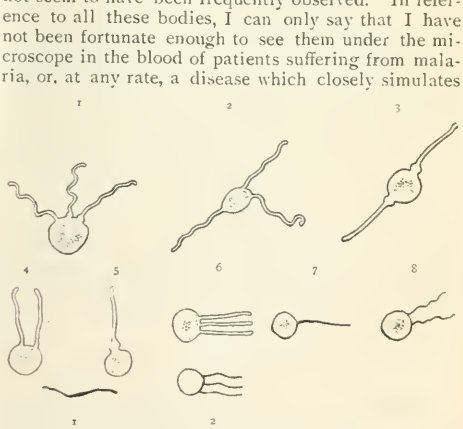
THE ALLEGED FLAGELLATE MALARIAL PARASITE VERSUS THE AMŒBOID CONTRACTILITY OF THE RED BLOOD CELL.

By W. MOSER, M.D.,

PATHOLOGIST TO ST. CATHARINE'S HOSPITAL, BROOKLYN, N. Y.

RECENT writers on the plasmodium malariæ have drawn attention to alleged peculiarities which their flagella possess. These characteristics, according to some observers, are the following: 1. The marked activity of the flagella. 2. Their symmetry as to length and form. 3. A singular dilatation at the point where the flagella arises from the body of the parasite (best seen in No. 3 of the illustration). 4. Their club-shaped extremities. 5. The fact that a flagellum may break off from the body of the parasite and circulate with a spirillum-like movement free in the blood plasma.

The figures from No. 1 to No. 8 were copied from different works on this subject, and were drawn for me by Mr. Charles Perpente, and show that all these peculiarities were not always met with. The most constant feature which they possess, and I admit that it furnishes some evidence that these flagellate bodies are parasites and not cells, is their symmetry as to length and their marked activity. In Nos. 7 and 8 of the figures it will be noted that the flagella are not club shaped and do not show the singular dilatation already referred to. The fact that a flagellum may break off and circulate free in the blood plasma does not seem to have been frequently observed. In reference to all these bodies, I can only say that I have not been fortunate enough to see them under the microscope in the blood of patients suffering from malaria, or, at any rate, a disease which closely simulates



it and is almost invariably improved by the administration of quinine. This fever occurs frequently in Maspeth, Long Island. I am inclined to believe that we may not always be dealing with the same disease. To show the similarity which the red blood cell itself may have to this parasite, I have added two illustrations, marked Nos. 1 and 2 in the third series. No.

2 was taken from a patient whose blood I frequently examined during life, and shows a red blood cell with three symmetrical or nearly symmetrical flagella, and which bears some resemblance to the alleged parasite above it (No. 6). The flagella in this cell were active, yet I cannot state that they were markedly so, a supposed characteristic of the parasite. The cell body was not pigmented. The patient was markedly anæmic during life, and I mention this to draw attention to the amœboid contractility of the red blood cell at the temperature of the air in most forms of profound secondary anæmia (carcinoma of the stomach, etc.).

In this case the autopsy was performed by Dr. Linder, and showed acute pericarditis, chronic parenchymatous nephritis, the "sago spleen," and a few tuberculous deposits at the apices of the lungs. The liver was in a condition of passive hyperæmia. No. 1 shows a red blood cell contracted like a spirillum, and was seen in a case of pernicious anæmia. I may mention *en passant* that in no other condition can the amœboid movement of the red blood cells be better seen than in pernicious anæmia. I wish to draw especial attention to this form of amœboid contractility, since it is not frequently met with, and may lead even an experienced observer into error. To designate this the spirillum-like contractility of the red blood cell may not be amiss. When I first saw this it seemed improbable that this really active cell was not some form of parasite. It seems to me that the white blood cell does not exhibit amœboid movement so frequently at the temperature of the air, I mean in diseased conditions, without the blood being kept at the body temperature, as do the red cells. They (the white cells) may do this, however, in some conditions oftener than in others. Manson has seen amœboid movement in the white blood cells (phagocytes) in malaria. Coronado studied the blood in yellow fever, and found in fatal cases just before death amœboid movement in the white blood cells—"full of phagocytic life." Amœboid bodies which stain with methylene blue have been produced in the red cells experimentally (C. Schwalbe). But whether a body like No. 3 of the first series could be produced experimentally, I am not prepared to say. It has occurred to me that what some writers describe as the endogenous (intracellular) formation of the plasmodium could be the endogenous formation of the cell itself.

In conclusion, I would state that I have not noted that symmetry and activity in the flagella of the red blood corpuscle so constant as writers depict for the alleged parasite. When the cell itself sends out two or three amœboid processes, asymmetry as to length and form is the rule. While I concede these differences, I do not regard them as sufficient evidence to prove that they are not cells. Since the plasmodium is supposed to develop endogenously (intracorpuscular), it may be unreasonable to expect their isolation and reproduction on artificial media. Laveran himself has not seen bodies which have been described and depicted as different phases of his parasite. While there may be a parasite in malaria, it ought to be, it seems to me, a morphologic unit, throughout the world. And what constitutes this unit?

158 Ross Street, Brooklyn.

Operative Route for Injury of the Kidney.—Dr. H. O. Walker is of the opinion that the most practical route to the kidney is anteriorly. The selection of the lumbar route is largely by precedent and unnecessary timidity on the part of the operator. A nephrectomy for tuberculous kidney is not always practicable. Fixation of a movable kidney by stitching its reflected capsule to the muscles is much to be preferred to that of transfixion and anchorage by stout ligatures.

DESCRIPTION OF SPECIMEN TAKEN FROM A HERMAPHRODITE.[1]

By CARL BECK, M.D.,
NEW YORK.

On July 25, 1896, I made a clinical report in the Medical Record of a case of hermaphrodism. The case concerned an individual twenty-one years of age, upon whom I had performed laparotomy for retained testicles, which had undergone sarcomatous degeneration. Excessive hemorrhage, caused by tearing the many adhesions present, rendered the patient pulseless during the operation, and compelled me to close the abdomen as quickly as possible, thereby preventing me from making the minute intra-abdominal examination that was desirable.

In view of this I hesitated to say in my former article that I was positive in having palpated and seen the ovaries, etc. But the patient acquired pneumonia eighteen days after the operation, and died three days later. The autopsy corroborated my statement in regard to the presence of the uterus, and also showed ovaries, tubes, and ligaments (see Fig. 1). Unfortunately, I was absent in Europe at the time of the autopsy, and the attention of the gentleman who made it was not sufficiently called to this most important point. Thus the ovaries, being very small, were not noticed and were cut off, only a trifle of the left one remaining with the specimen. The tubes and ligaments, however, are so well preserved that even the mutilated specimen demonstrates them (Fig. 2).

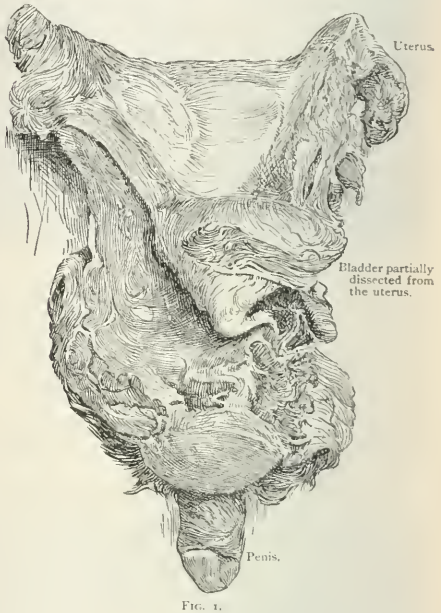


Fig. 1.

The uterus measures two and one-fourth inches in length. The fundus is one and one-fourth inches and the cervix a little less than one inch wide. It consists of the three normal strata, viz., serosa, muscularis, and mucosa. The uterine canal is two inches long and the endometrium shows ciliated epithelium down to the middle of the canal and laminated pavement epithelium below. No ostium tubæ uterinum could be made out in the fundus uteri, nor did the Fallopian tubes show the presence of a canal. An

[1] Demonstrated to the New York Pathological Society, October 14, 1896.

ampulla showing fimbriæ could be recognized on each side. The ovaries were of an elliptical shape and of unusually small size. A ligamentum ovarii was well developed on either side, as were also the broad ligaments. No parovarium was noticed. The short fragments of the round ligaments are still plainly visible on the specimen. The labia majora are extremely well developed, as is evident from Fig. 3. (The photographs Nos. 1 and 2 in my previous article, which were taken in the hospital, do not show them satisfactorily.) The inner surfaces of the labia show the presence of sebaceous glands. No trace of Bartholin's or Cowper's glands could be found. The escutcheon or arrangement of the pubic hair was not feminine, and was not continued up to the umbilicus. The urethra was of the female type. Dissection of the penis revealed the presence of two corpora cavernosa. From the inner surfaces of the tunica albuginea and of the septum a large number of trabeculæ branched off, which consisted of muscular and smooth elastic fibres and of connective tissue. There was no urethra connected with the penis, nor a corpus cavernosum urethræ. The prostate was small and very hard, but well developed. It had the shape of a small chestnut, consisted largely of connective tissue and smooth muscular fibres, and showed but few blood-vessels. Its presence gave the normally developed bladder the male type. The funnel, the posterior wall of which it formed, led into a blind pouch, while from the anterior wall the urethra branched off. No seminal vesicles were found. Still it might very well be that rudiments were present which could not be demonstrated in the spoiled specimen. The glans penis is also well developed, only the prepuce being of small size.

The tumors which were removed by laparotomy have to be regarded as testicles, according to the history. Microscopical examination alone could not show the character of the organs on account of their tissue change. Eminent pathologists, like Drs. Prudden, Ely, Brooks, and others, did not care to express any definite opinion as to the microscopical part of the question. From the microscopical report of Dr. Henry Brooks I quote the following: "The tumor is composed of mixed elements, making it in my opinion quite impossible to classify it exactly. In some portions it has the typical structure of alveolar sarcoma; in others, again, it has a dense fibrous structure, which I take for including capsule. In addition there is a number of large foci of well-formed cartilage tissue, such as is seen in the bronchi and trachea, and several larger of the smaller areas are occupied by glandular structure showing typical epithelial cells of columnar or cubical form. The bulk of the growth is composed

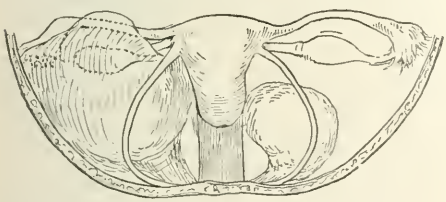

Fig. 2.—Appearance of Parts at Time of Operation.

of embryonic tissue, and I am inclined to think the growth belongs among the teratomata or so-called blastomata."

It may also be mentioned in this connection that the short pedicles of both tumors were very vascular, bearing a resemblance to the plexus pampiniformis.

It may be added that the pelvis, as well as the gluteal region and the thighs, was of the male type. The panniculus adiposus was but little developed, for which the cachexia, however, might be responsible. The larynx was not prominent. The family history of the patient was good.

It is not at all certain to me whether menstruation took place or not, as the person, who was very intelligent, did not wish to be taken for a girl. The possibility cannot be excluded, and the subject might have had a trace of it and denied the fact.

Very few cases like this are reported in literature. There is a specimen in the anatomical museum of Würz-

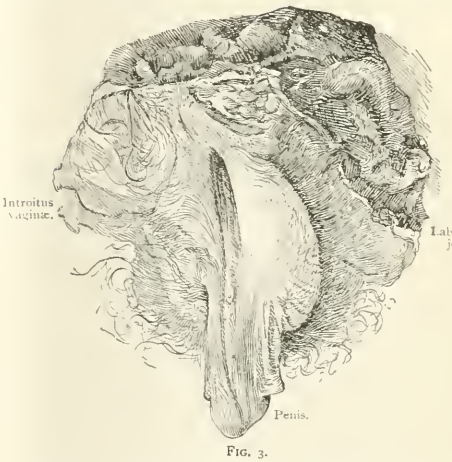

Fig. 3.

burg, in which male and female organs (penis, pars prostatica, vagina, and Fallopian tubes) were present.[1] There is another case, reported by Zweifel, showing the same condition at the autopsy. It concerned a child, six months of age. Similar cases are reported by Ahlfeld.[2] I may also refer to the well-known cases of Heppner[3] and of Meyer,[4] of Zurich. Dr. H. J. Garrigues[5] speaks of an individual, now alive, who not only menstruated, but possessed semen. The left side of this individual looked like a male, and the other side like a female.

It seems to me that such cases are more frequent than is generally supposed. During lifetime the observers must to a great extent rely upon the veracity of the patients' reports, which are but exceptionally corroborated by an autopsy. If, as in this case, there is nearly complete atresia of the vagina, which was accidentally discovered, the facts generally remain unnoticed.

In conclusion I desire to thank Drs. Prudden, Ely, Brooks, Torek, and Lusk for their kind co-operation.

Fracture of the Internal Condyle of the Humerus.—I am firmly convinced that it is desirable practice to postpone passive motion until the intermediate callus is firm enough to prevent motion at the seat of fracture. Postpone passive motion for from eight to twenty-one days, in the child; in the adult, for three or four weeks. It is by securing rest for the fracture that we diminish as far as possible the amount of exuberant callus so often in the way of an ideal functional result.—Dr. Senn.

Clinical Department.

DIPHTHERIA AND SCARLET FEVER.

By G. E. DALY, M.D.,

NEW YORK.

The writer desires to report a series of twenty consecutive cases of diphtheria which have come under his care since May 1st of this year. The twenty cases referred to occurred in seventeen different households. All of the affected were children, the oldest being twelve years of age, and the youngest slightly over a year. The latter child was suckled occasionally by its mother, but at other times, and more frequently, was fed from a bottle. The average age of the affected children was two years and six months.

All presented the clinical evidences (membrane, etc.) of diphtheria, and the diagnosis in each case was confirmed by bacteriological examination of the health department.

The children were, with one exception, seen on the first or second day of the appearance of the membrane. The case excepted was first seen on the seventh day of the disease.

In nineteen of the cases the plan of treatment pursued was as follows: namely, to administer to the sick children one-tenth-grain doses of calomel every hour until a fæcal evacuation had occurred, in the mean time giving every two hours liberal doses of the ordinary iron, chlorate of potassium, and glycerin mixture, and constantly applying, when the child would permit, hot flaxseed poultices to the exterior of the throat.

Further, the health department had been notified of the existence of the disease, and each sick child, as well as the non-affected children of the same household, was injected by the health department, at the solicitation of the writer, with antitoxin.

The nineteen diphtheritic patients so treated promptly recovered, though several had been affected by the severe type of the disease, having extensive exudations, etc.

There were no resulting or accompanying complications in any of the cases, excepting for a slight pharyngeal paralysis in a boy of eight years.

The twentieth case, being the second of this series, was first seen after the disease had been in existence one week. In this child's throat a very general naso-pharyngeal and palatal exudation existed, and the child was in a nearly unconscious condition as the result of exhaustion and sepsis. The case being regarded as hopeless, antitoxin was not injected, though the other measures of treatment were carried out, but without avail, as the child died thirty-six hours after the beginning of treatment. It is probable that even had antitoxin been injected the child's life would not have been saved.

The writer has observed absolutely none of the ill effects that are said frequently to follow the use of antitoxin, although he has had under observation not only the nineteen sick children in whom the remedy was used, but also twenty-four other children, members of the same families or of disease-stricken households, to whom immunizing injections of antitoxin were administered.

In support of the immunizing power of antitoxin, the writer would say that in only three households did second cases of diphtheria develop, and in two of these three cases the children who became secondarily affected were feverish and apparently already infected by the diphtheritic process before antitoxin had been used upon them. From these two examples it may be inferred that injections of antitoxin have not the power of aborting diphtheria once the infection has occurred, although slight fever may be the only evidence of the approaching disease.

The third case gives this history: On July 5, 1896, Ida C——, aged ten years, was found suffering from a marked naso-pharyngeal diphtheria. Antitoxin, etc., was used for its treatment, and the other children of the household were ordered immunized. The girl recovered without complications. On July 27th (same month) her brother, aged twelve years, was reported sick and found to be suffering from diphtheria. Upon inquiry it was learned that when the physician of the health department had on July 6th injected the other members of the family with immunizing doses of antitoxin, this boy had run off, and had therefore not been so injected, but, as above recorded, later developed diphtheria, the only secondary case that occurred or has since occurred in that household of seven children.

From such a history a possible power of immunization from diphtheria might reasonably be attributed to antitoxin injections.

The day following the writing of the preceding paragraph, one of the children referred to as having recovered from diphtheria became sick, and after ailing for twenty-four hours developed a fever of 100° F., pulse of 120, with some suffusion of the eyes, and a rash, which appeared first on the face and later on the upper and lower extremities, but not at all upon the body. It was rose colored, like that of measles, and had a distal bordering of small and discrete papules, which proximally were preceded by patches as large as a half-dollar, and these by patches which had become confluent and erythematous areas raised wheal-like above the plane of the surrounding integument. There was no itching, as in urticaria; the lateral neck muscles were fixed and rigid, and the right knee-joint was much inflamed and painful as in rheumatism. The child had never had measles.

The question presented itself as to whether the child was developing rubeola or suffering from an urticaria, such as has been reported as resulting from antitoxin injections, though in this child antitoxin had been injected but once, and that two weeks before the development of the rash in question, which latter had become manifest after a seemingly prodromal period of not more than twenty-four hours' duration. A positive diagnosis was not made. Salicylate of sodium was prescribed, and on the following day all of the rash and rheumatic symptoms had disappeared and have not since recurred. Rubeola could not have been so aborted; hence the rash, so extensive but of so temporary a character, was probably urticarial.

The question still remains as to whether it and the joint symptoms, simulating an infection of some kind, were caused by the injection of antitoxin fourteen days before, or whether they arose from some other cause.

And now referring to scarlatina. There frequently occurs in scarlatina a type of sore throat, the severity of which seems not at all to depend upon the grade of the febrile disorder, in that the throat manifestations may be quite extensive and accompanied by but a slight fever, a fleeting rash, etc.

The throat disease in question is of an exudative (?) character, and may be seen upon the uvula, soft palate, tonsils, or posterior pharynx. It has all of the usual appearances of a diphtheritic membrane, and with scarlet fever is undoubtedly the condition so commonly termed "scarlet fever and diphtheria."

The writer, having remarked for some years that when this so-called association of scarlet fever and diphtheria occurred the affected children almost invariably recovered, was at a loss to understand why, when the mortality of diphtheria alone averaged from thirty to fifty per cent. of those affected, that of the

same disease complicating scarlet fever should have a so much lower mortality rate.

Accordingly, since the first of the year, the writer, with the assistance of the health department, has had cultures made from the throats of all patients having scarlet fever in whom the throat exudations were such as would have led one, knowing nothing of the existing scarlet fever, to have diagnosed the throat condition as that of diphtheria. In all such cases, the invariable bacteriological report has been that no bacilli of diphtheria were found, but that there were found bacilli of a variety resembling those of diphtheria. If but one or two such reports had been received, considerable doubt might have existed as to whether the bacilli mentioned were not actually those of diphtheria; but as several such reports have been received, and, as already mentioned, the mortality for the conjoined (?) diseases is much lower than that of the more serious when not so associated, the writer has become somewhat doubtful as to the actual occurrence of both diseases at one time and in the same patient.

In other words, here are two diseases: one serious, the other more so, with death resulting frequently from either, and yet the attention of the physician is frequently invited to the inspection of children who are said to have survived a simultaneous seizure of both.

SOME INTERESTING VARIATIONS IN THE FLEXOR AND EXTENSOR MUSCLES OF THE FOREARM.

By EDWARD JUDSON WYNKOOP, M.D.,

LATE HOUSE SURGEON, NEW YORK POST GRADUATE HOSPITAL; DEMONSTRATOR OF ANATOMY, COLLEGE OF MEDICINE, SYRACUSE UNIVERSITY.

The following condition was noted in the flexor and extensor tendons and muscles in a male subject: The most interesting variation was the peculiar division of the flexor sublimis digitorum. The flexor sublimis digitorum arises as practically four distinct muscles or heads. The outer head or muscle arises by two heads, one from the oblique line of the radius above the insertion of the pronator radii teres, the other from the common tendon from the inner condyle of the humerus. These heads unite and become tendinous, and the tendon passes to its insertion in the second phalanx, dividing before its insertion to allow the tendon of the flexor profundus to pass through it on its way to the last phalanx. Just where these two muscular heads unite, a strong tendon is given off and passes to and blends with the flexor longus pollicis.

The next muscle or second head, from without inward, at its origin resembles more in its common characteristics the flexor sublimis digitorum. It arises from the common tendon and the internal lateral ligament of the elbow-joint, soon becomes tendinous, and when about half-way down the forearm widens out into a muscular belly which is about two inches in length. The muscle becomes tendinous again and passes to its insertion in the index finger. From the small muscular belly above referred to, a tendon arises which passes to its insertion in the little finger. The third or most internal head or muscle arises from the common tendon and passes down the forearm to its insertion as an entirely separate muscle. The insertion of this muscle is in the ring finger.

The relation of the tendons passing under the annular ligament of the wrist-joint is as follows: The tendons passing to the index and middle fingers are anterior: those passing to the ring and little finger are posterior.

The flexor profundus digitorum is normal except that it becomes tendinous very high up in the forearm.

The extensor minimi digiti is wanting. The extensor ossis metacarpi pollicis has an additional tendon which arises from the anterior and outer border of the radius.

In the foot an extra tendon was given off from the extensor proprius pollicis and was inserted into the first phalanx of the great toe.

In looking over the records I can find no account of a similar condition. To Mr. Gere, a student, I am indebted for the excellent dissection.

ACUTE ALCOHOLISM AND TRAUMATISMS.

By JOHN B. HUBER, A.M., M.D.,

NEW YORK,

FORMERLY CORONER'S PHYSICIAN OF NEW YORK COUNTY.

Mistakes in the diagnosis between acute alcoholism and traumatisms are not uncommon. The patient is supposed to have been suffering from the former when autopsy reveals extensive internal injury, to the mortification of the surgeon and the delectation of the representatives of the lay press.

An instance of the importance of this subject from the medico-legal viewpoint is the following: A medical examiner of another city, whose position is akin to that of a coroner's physician of this city, reports a case in which he found no external marks of violence. Upon such inspection and after hearing testimony which appeared to him conclusive, he, without making an autopsy, gave a certificate of death from alcoholism. After burial upon this certificate, further testimony was produced that the deceased had been struck upon the head during a drunken brawl. The body was then exhumed, and upon autopsy an extensive cerebral hemorrhage was found. It seems that the assailant's weapon fell first upon the stiff hat of the deceased, and that thus no contusion was made. Arrest, trial, and conviction followed.

The diagnosis is often difficult and at times quite impossible to make, the symptoms of alcoholism in many cases simulating those due to traumatism. Often the surgeon must decide upon the spur of the moment, while in the midst of an excited and a perturbing crowd. Or the patient may be lying in a dark or insufficiently lighted cell in a police station. Or the alcoholism may be evident enough, while the concomitant traumatism may be obscured by its presence and may thus pass unrecognized.

In uncomplicated acute alcoholism there will be the odor of the breath, the temperature will be subnormal, the pulse slow and labored, and the respiration stertorous; the pupils will probably be dilated, but may be normal or contracted: they are not likely to be unequal. The tongue will be furred, there may be vomiting of food and alcohol, the face will be bloated and flushed if the debauch has been recent, otherwise the skin will be pale and clammy. The motor power will be partially or entirely lost, and the entire muscular system will be involved in the change, and there will be drowsiness merging into insensibility.

If subjective symptoms can be elicited, headache, dimness of vision, anorexia, uneasy sensation in the epigastrium, lassitude, and depression will be complained of.

Finally there may be the familiar phenomena, delirium tremens.

As to traumatisms: First, the body should be inspected, especially the head and neck, for marks of violence; for that purpose the clothing, at least that portion covering the vital parts, should be removed. External injury suggests the possibility of grave internal lesion, and justifies the transfer of the patient for further examination. However, no mark of vio-

lence may be found upon the closest inspection; a fracture of the skull or a hemorrhage within the cranium may have no outward sign. Or a heavy wagon may pass over the body, fracturing the ribs, rupturing the liver, perforating the intestines, or injuring other vital organs without producing any external mark.

In grave internal injuries of the trunk, as indeed in all cases of severe trauma, there will be symptoms of shock. Primary shock, following right upon the injury, will exhibit a subnormal temperature and a small and fluttering pulse. The patient will be faint and trembling, there will be nausea and vomiting, the skin will be cold and clammy, and the sphincters will be relaxed. Secondary symptoms are dyspnœa and tumultuous heart action, headache, sleeplessness, and a diminution of mental powers.

As to injuries of the head: It is not within the scope of this paper to present a symptomatology of cerebral hemorrhage, brain laceration, and other results of traumatism, varying as such symptoms do with different stages and the site and extent of the lesion, and often closely simulating the signs of acute alcoholism. The phenomena about to be described are referable only to head injuries and are not likely to be found in uncomplicated alcoholism. Depressed fractures at the vertex will be detected upon palpation. Fissured fractures may be found upon inspection, with the help of an incision if necessary, or the finger nail or a probe may be passed across the surface. When the blood is wiped from a suspected part and no fresh blood appears, there is simply a suture; if fresh blood oozes to the surface, there is a fissured fracture.

In fracture of the base there will usually be found hemorrhage from the nose, mouth, and ears, and ecchymosis into the conjunctiva or subcutaneous cellular tissue; or vomited blood may have been swallowed after fracture of the ethmoid or sphenoid, followed by hemorrhage into the posterior nares. But absence of such hemorrhage does not necessarily indicate absence of fracture. A rare but positive symptom of fracture of the base is the escape of a watery fluid, probably cerebro-spinal fluid, often copious in amount, from the ears, the nose, or the mouth.

Fracture of the petrous portion of the temporal bone involving the tympanum may produce in the temporal or mastoid region a pneumatocele, a smooth, circumscribed, resonant, non-fluctuating tumor. Among intracranial affections, "cerebral irritation" presents characteristic symptoms; it usually follows a blow upon the forehead or the temple, and is probably associated with laceration of the cerebral substance, more especially, of the gray matter. The patient lies on one side, is restless, with the extremities flexed, the eyelids firmly closed. If the eyelids are forcibly opened, the pupils are found contracted and intolerant of light. The surface is pale and cool, or even cold. The pulse is small, feeble, and slow. The patient is irritable, muttering, and grinds his teeth when disturbed. The sphincters are not usually affected, and there is no stertor.

There will be a rise in temperature in head injuries, except in primary shock and in large uncomplicated hemorrhage, when the temperature is likely to be subnormal.[1]

Other signs of intracranial lesion are photophobia, with the eyelids firmly closed, intolerance of sound, the carotids beating forcibly, a blowing of the lips, and a flapping of the cheeks, rigid contraction of limbs, and clonic or tetanic convulsions. The Cheyne-Stokes respiration is found in injury to the brain and cerebral hemorrhage. The breathing becomes by degrees deeper and more rapid up to a certain point, and then subsides in the same gradual manner until there is a complete cessation of respiration, with a deep silence, the pause before the next respiration lasting a variable time.

Unilateral phenomena point to intracranial lesions; for instance, unequal pupils or ptosis of one eyelid or drooping of one corner of the mouth. In intracranial lesions there is apt to be found in the radial pulse a want of symmetry in fulness and strength upon the two sides of the body.[1]

In conclusion, when in doubt act as if the case were one of traumatism. And in a suspected case keep the patient under observation until the effects of a debauch have worn off; symptoms of head injury, which may have been masked by the acute alcoholism, may then become manifest.

72 West Forty-Seventh Street.

FOREIGN BODIES IN THE AIR PASSAGES.

By CYRIL FULTON, C.M., M.D.,

Fort Covington, N. Y.

On October 6, 1896, a patient, seven years of age, was brought to my office by his father, with the following history: While playing with some shingle nails, the little fellow placed in his mouth one which suddenly slipped backward. He was seized with a violet fit of coughing. The father ran to him, saw there was something choking him, and passed his finger into his throat as far as he could, when the coughing ceased. He then brought the child to me, a distance of three miles. I examined the throat carefully but found nothing. He had no cough or difficulty in breathing, and was in no way inconvenienced. I was forced to conclude that the nail (if he had had one in his mouth) had passed into the œsophagus, providing he had not expelled it. He said the nail was an old one and slightly bent. I gave instructions to put him on a diet which would leave a large residue and carefully watch all stools for appearance of the nail.

Next day I saw the father again. He said the child was complaining of nothing. There was no cough or change in breathing.

The following day, October 8th, when passing the house, I was called in. The mother informed me that about 5 A.M. that day the child had a violent attack of coughing. They rushed to his bedside, when the coughing ceased and the child remarked: "I have spit up something about the size of a pumpkin seed." There on the bed lay a wire shingle nail, one and a half inches long, slightly bent and wet.

I carefully auscultated the chest. I found no change in respiratory murmur. He had no cough, no elevation of temperature, and no indication of anything having taken place.

I reported the case to a confrère, who is a specialist on the throat, and give the following extract from his letter to me:

"Curious to relate, the following day after I received your letter, I was told by the mother of a little patient that her child had bitten off the end of a thermometer, and, it was thought, had swallowed it, but as nothing appeared in the stools subsequently, and the child seemed in no way inconvenienced, nothing more was done until a week or ten days afterward. The child coughed it up."

This second case is apparently similar to my own, the only difference being that the foreign body was retained longer.

It seems almost impossible that the articles were lodged in the trachea. In the first place we would look for greater spasm of the glottis on the entrance of the foreign body, and secondly, it would give rise to more

[1] Ibid.

pronounced symptoms when nature attempted its removal, especially in the first case, since the parent's finger may have aided the introduction. We know that the symptoms of entrance of a foreign body into the larynx gives rise first to a violent suffocation, which subsides as soon as the body sinks into the chest, but is renewed every time it is coughed up into the larynx. The absence of symptoms is due to the difference in the innervation of these parts. The mucous membrane of the larynx and the laryngeal aspect of the epiglottis are supplied by the superior laryngeal nerve, while the lingual aspect of the epiglottis receives its feeling from the glosso-pharyngeal. The epiglottis acting as a valve in the act of swallowing, closes the air passages, and any article may come in contact with its upper surface without giving rise to any discomfort.

On the other hand, if the slightest particle of food or a drop of liquid slips past and touches the mucous membrane of its under surface, or of the larynx itself, then we get violent coughing, and, if a foreign body gain admission to the larynx, immediately come on spasm of the glottis, suffocation, lividity of the face, and appearance of impending death. The mucous membrane of the trachea and bronchi is less sensitive, being supplied by other branches of the vagus given off lower down, and a foreign body may lie there, giving rise to no symptoms until inflammation sets in. The same spasm that we get on its introduction will be repeated, however, every time the foreign body is coughed back into the larynx, and we should hardly expect such an easy removal as we have had in both these cases.

Query: Where had the foreign bodies been?

REMOVAL OF THE OVARIES IN INSANITY.

By FRANK BLAISDELL, M.D.,

GOFFSTOWN, N. H.

The following case may be regarded, I think, as a contribution to the statistics of removal of the ovaries for insanity, although the operation was done for diseased conditions, and not for the express purpose of benefiting the mental condition.

C. F. M——, aged twenty-seven years, was admitted to the Hillsboro County Hospital on October 16, 1895. She had been in good mental condition as a child, and remained so until her marriage and the birth of a child in 1893. At this time she had domestic troubles, became melancholy, and developed soon after an acute mania. She became destructive and restraint being necessary, she was sent to the hospital.

Soon after I took charge of the hospital in October, 1895, my attention was called to her by the nurse, as she was complaining of abdominal pain and was fast becoming bedridden. This pain had persisted since the birth of her child.

Efforts were made to relieve her by medication, but failed, and a thorough examination was made which resulted in finding both ovaries enlarged to the size of lemons and exquisitely tender, and also an enlargement of the right tube. Removal was advised and consented to by her friends, and on March 25, 1896, assisted by the hospital staff, I did a double oöphorectomy with a left salpingotomy. The uterus was healthy and was let alone; both ovaries were in a bad state of cystic degeneration, as was the left tube, and they were removed. Recovery was uneventful, the pulse never going above 90 nor the temperature above 100° F.

After the first week a most gratifying change was noted in her mental condition. Her mind recovered its natural balance, and she is to-day mentally sound, and is presiding over her own home, a happy wife and mother.

PSYCHICAL SEIZURES IN EPILEPSY.

By L. PIERCE CLARK, M.D.,

ASSISTANT PHYSICIAN, CRAIG COLONY, SONYEA, N. Y.

It has come to be a fairly well-established fact that neurologists who fail to take into account the mental characteristics of epilepsy fail to study the disease in its entirety. Not only is it necessary to take into account the kind and degree of mental change to form an accurate opinion of the prognosis in a single case, but it is also essential that we study the mental characteristics in order to treat the case understandingly.

Much has been written during the past few years upon psychical epilepsy: it is sometimes considered to be a distinct psychological entity, but much proof is still wanting. Again, mental disturbances are supposed to take the place of a true convulsion, and this gives us the form of epilepsy known as epilepsia larvata or masked epilepsy. The writer is not aware of any neurologist or alienist who as yet maintains that this form of epilepsy is still more than a hypothesis which lacks much of true demonstration. Leaving out this so-called psychical equivalent in epilepsy, we have yet a very important and delicate manifestation of epileptic phenomena which it is the writer's purpose to consider in this article.

Psychical attacks might properly be termed that form of disorder of consciousness seen in epileptics in whom no muscular convulsion is perceptible. It is very difficult to recognize these attacks and properly to diagnose them if they are seen in any subject who is not also afflicted with other forms of seizures, such as grand mal and petit mal. Indeed, there is no doubt that many of the so-called homicidal attempts which come to light in the criminal courts are attacks of this kind, which may be very uncommon in the subject's life but are associated with certain forms of excitement or stimulation. It is rare for an epileptic to have nothing but psychical attacks, as they are generally associated with petit mal and occasionally with grand mal.

Let us look at some illustrations of true psychical seizures.

Case I.—H. G——, a patient recently admitted to the Craig Colony. She states that she has seizures in which she has a feeling of constriction across the forehead, and during these attacks her conception of the arrangements of the room in which she happens to be and of the people who chance to be in the room at that time is different from that which she has in the normal state which just precedes them. She further states that she is not entirely conscious of what she says and does at these times, and is very apt to express ideas antithetical to those which she really entertains. In the period of normal consciousness which immediately follows these attacks, she remembers what she has said and often makes an effort to correct the wrong ideas that were expressed. Psychologically such attacks must be similar to alternating states of consciousness known as double personality. In this case, psychical attacks are three times as frequent as regular grand-mal seizures. She rarely has an attack of petit mal. Probably consciousness suffers only a slight disorder or attenuation, and is not entirely lost throughout the whole attack.

Case II.—R. K——. Patient is afflicted with psychical attacks which are described as follows: When you happen to ask her a question, she does not answer it, but after the attack has passed she is certain to ask you what your query was about. She recollects that you have spoken to her, but she fails to grasp the meaning during the attack. The onset and course of these attacks are often described in such words as "They come and go like a wave," which is a very accurate and satisfactory description. This patient often

has a psychical aura which consists of the words "nicht wiedersehen." It has preceded her light attacks for the past year. Occasionally the words "auf dem reirdem" are present as an aura. She further states that there is no apparent connection between the recurrence of these words and normal thought of every-day life; she does not even know the meaning of the phrases and the cause of their recurrence at such times is inexplicable. The true explanation is probably this: In early life, prior to the onset of her epilepsy, she has associated with Germans and her mind has been surcharged with German phrases, and now, when consciousness is partially lost, these phrases rise to the surface of normal every-day thought—an illustration of morbid unconscious cerebration. She never has insistent ideas, word dominance, or phrase rhythm in her normal state. At no time have these recurrent phrases been present after the attack or in the interim.

Case III.—W. P——. Patient has such slight attacks that they are perceptible to no one. He states that he frequently has a slight attack while reading a single line of print, and that before he has finished the line normal consciousness will have returned. He says that he is made aware of having had an attack by suddenly realizing that he has not understood the last three or four words of the line he has been reading and is obliged to reread them for the lost thought.

These seizures I regard as typical ones of psychical attacks. They are occasionally classified under the broader type of petit-mal epilepsy, but would seem of sufficient importance and distinction to merit a separate classification. We find closely associated with these psychical seizures many of those varied disordered states of consciousness known as epileptic vertigo, somnambulism, and automatism. At times they shade off into each other, and it is difficult to find any distinct line of demarcation.

Many authorities state that these psychical seizures are necessarily of a more severe and disastrous nature because these disturbances are in the higher realms of cerebral activity. They also state that dementia and disturbances of the normal mental processes are a more frequent sequence to such epilepsies. This is not borne out by clinical observation. It is not infrequently observed that attacks of epileptics of the grand-mal type, when under proper care and treatment by bromide, pass into the petit-mal variety, and finally shade off into psychic seizures. To all appearances the subjects are on their way toward improvement and recovery. Many cases of epilepsy in which psychical seizures predominate show but little dementia or other evidences of mental degeneracy, although they may have had their psychical attacks for several years. It seems to prove that such attacks are slight and are not in the higher realms of cerebral activity. The severity of an epileptic seizure is best indicated by the degree and length of time that the disordered consciousness obtains than by any other symptom in epilepsy.

The principal reason why psychical seizures have been classified with the severer forms of epileptic attacks, and most to be dreaded, is because they frequently occur in neurotic families in which there is a marked heredity to convulsive diseases. In such cases epileptic mania and dementia are not far distant.

In regard to the prognosis of epilepsy in which psychical attacks predominate, it is unfavorable as to recovery, but a far better prognosis can be entertained as regards life in such epilepsies. Epileptics having psychical attacks are not subject to as many injuries and complications resulting from falls and exposures, as are ordinary grand-mal epileptics. Again, if psychical seizures make their appearance in epileptics who have no bad heredity, the chances for recovery would seem to be fully as good as in cases of other forms of epilepsy. Mental disturbance is not necessarily a more frequent sequence in such attacks. It would seem, therefore, that there are two distinct kinds of psychical seizures: 1st, those seen in epileptics of neurotic family, in which the first attacks are psychical; in such, the prognosis for recovery is bad; 2d, those grand-mal or petit-mal epileptics whose psychical attacks become more frequent as the case improves.

The treatment of psychical seizures is very simple. They are but little or not at all modified by the administration of drugs. The moral treatment is undoubtedly of great value, especially that which is embraced in some regular manual labor daily performed to the point of bodily fatigue. All things which have a tendency to stimulate the higher mental activities are especially to be avoided in the treatment of psychical epilepsy, as such epileptics are prone to mental excesses. The patient must be relegated to a simple mode of life and made to perform ordinary manual labor, and the diet should be very simple and non-stimulating. Long hours of sleep should be enjoined. Massage and cold douches in the cervical region are sometimes of benefit. As such epileptics are often subjects of exaggerated self-feeling, it is essential that they be made to perform work that will require their attention to such a degree that they will have less opportunity for self-commiseration. All things which exalt the emotional side of life should be positively forbidden.

ALCOHOLIC CHOREA.

By W. MOSER, M.D.,

BROOKLYN, N. Y.

Alcoholic chorea, as its name implies, is caused by excessive indulgence in alcohol. The attacks are usually seen in individuals shortly after a prolonged debauch. The individual who goes on a "spree" now and then is more apt to be attacked than the habitué. Choreiform movements may persist after an attack of delirium tremens.

Symptoms.—The symptoms resemble the chorea sancti Viti or St. Vitus' dance, so frequent in children. Owing to clonic contractions in the muscles, involuntary movements now of one part of the body, then of another, are constantly taking place. In the few cases under my observation, the patients could not keep their hands quiet; they were incessantly making peculiar movements with them and tossing them about. Contrary to infantile chorea, they often placed their hand on the throat, as if something were choking them. When asked why they do this, they answer that there is "something" in their throat choking them, which they vainly endeavor to force either up or down. In one case this symptom was very prominent. Whether this symptom is dependent upon a clonic spasm of the laryngeal muscles I am not prepared to say. When a child with St. Vitus' dance is told to stop being so restless, the mother will say "the child can't help it." The same answer is given in this class of cases, and one man said to me, when I requested him to stop tossing his hands about, "I wish I could." The head is sometimes tossed about. These irregular clonic convulsions were associated with the characteristic alcoholic tremor, especially when they were told to hold out their hands.

Sleeplessness is a prominent symptom in these cases. As in infantile chorea, the movements cease during sleep. While hallucinations may have occurred during the debauch, in the cases of so-called alcoholic chorea which I have witnessed, the mind remained clear. Headache is not infrequent. Any excitement on the part of the patient aggravates the movements.

The diagnosis is comparatively easy When the patient will not admit that he has been drinking heavily, it could then be confounded with hysteria. The peculiar choking sensation in the throat which these individuals have reminds one of the globus hystericus. But the sleeplessness, headache, and tremor may be of aid in the diagnosis. It could be confounded with cases of severe paramyoclonus multiplex. Paramyoclonus multiplex usually follows some great emotional disturbance, as fright, etc., and usually occurs, according to Friedreich, who first described it, in young male adults. The tremor and other symptoms of alcoholism are absent.

Treatment.—As restlessness and sleeplessness are prominent symptoms, bromides and chloral are indicated. Hypodermic injections of strychnine are valuable. These should be followed by administering tincture of nux vomica, tincture of capsicum, compound tincture of cinchona, as in a favorite prescription of Loomis, for allaying the craving for drink.

The prognosis is influenced by the treatment and subsequent care of the patient. The movements may persist for a long while.

In conclusion I would state that I felt justified in giving this a special description, as some writers have done for alcoholic multiple neuritis, alcoholic paraplegia, or alcoholic epilepsy.

158 Ross Street.

Progress of Medical Science.

Progressive Multiple Localized Neuritis (Mononeuritis Multiplex).—Remak (*Deutsche medicinische Wochenschrift*, January 28, 1897, p. 68) describes as progressive multiple localized neuritis, or mononeuritis multiplex, a condition in which inflammation of several peripheral nerves remote from one another takes place successively, and he relates an illustrative case. A compositor, fifty-seven years old, presented progressive painless weakness, wasting, and sensory disturbance of the left hand of rather more than a month's standing. The previous health had been good, there was no history of syphilis and none of alcoholism; and there had never been any evidence of lead poisoning. Examination disclosed the existence of an amyotrophic process limited to the peripheral distribution of the left ulnar nerve. The muscles of the first interosseous space especially, and in less degree those of the hypothenar eminence, were wasted. The ring and little fingers occupied a slight claw position. Adduction of the thumb, abduction and adduction of the fingers, as well as extension of the terminal phalanges, were executed feebly, while the movements controlled by the muscles of the thenar eminence were well performed. Pain sense and temperature sense, as well as tactile sensibility, were diminished upon the ulnar aspect of the dorsum of the hand and upon the hypothenar eminence and the little finger. The ulnar nerve displayed no special tenderness upon pressure. Faradic and galvanic irritability of the nerve in the arm and in greater degree at the wrist were diminished, while the muscles of the hand supplied by the median nerve reacted normally and those supplied by the ulnar presented reactions of degeneration. For this condition no cause could be positively determined and it was concluded to be due to pressure during sleep. Improvement followed treatment with the galvanic current, but in a short time symptoms of a similar nature appeared in the distribution of the right crural and obturator nerves and progressively advanced. The urine was examined repeatedly, but no abnormality was found. Meanwhile the little finger of the right hand began to assume a claw position, with weakness in the adductors of this digit and also of the thumb, together with wasting and numbness and diminished electric irritability.

The Treatment of Ozæna.—Bruck (*Berliner klinische Wochenschrift*, January 18, 1897, p. 53) discussed the procedure recommended by Gottstein in the treatment of ozæna and describes a modification of his own. He points out that the object of local treatment in this disorder is not only the removal of adherent secretion, but also the prevention of its reproduction and desiccation, with the formation of crusts and the development of the characteristic fœtor. These ends can be best attained by periodically introducing into the nasal cavities tampons of absorbent cotton accurately adapted to the mucous membrane on which the secretion appears and the crusts form. The tampon acts by stimulating nasal secretion and by absorbing the discharge, thus preventing the formation of crusts and the resultant fœtor. The pledget of cotton is to be replaced by a fresh one as soon as it is saturated. A similar plan of procedure may be followed in cases of empyema of the antrum of Highmore, providing the discharge is not excessive. Only one nasal chamber is to be tamponed at a time, in order to avoid mouth breathing. Bruck has found that a useful purpose is subserved by maintaining a continuous tamponade, *i.e.*, the introduction into one nasal chamber of a folded strip of absorbent gauze not entirely occluding the naris, while the tampon of absorbent cotton is introduced into the other. In this way the inspired air is filtered, warmed, and rendered moist. This plan of treatment is only palliative, the effect continuing as long as the applications are made.

Resection of the Cervical Sympathetic in the Treatment of Exophthalmic Goitre and of Epilepsy.—Jonnesco (*Centralblatt für Chirurgie*, January 16, 1897, p. 34) has been led by the success attending partial resection and division of the cervical sympathetic in the treatment of exophthalmic goitre and of epilepsy, and by the frequency with which lesions of this portion of the nervous system are found in association with the diseases named, to undertake complete and bilateral resection. The first case operated on was one of exophthalmic goitre. The upper and middle cervical ganglia and the strand connecting them were resected on both sides. The good result (disappearance of exophthalmos, diminution of goitre, absence of grave manifestations, led to the repetition of the operation and the complete extirpation of the cervical sympathetic, *i.e.*, all three ganglia. Nine cases were thus treated: two of exophthalmic goitre, three of true epilepsy, one of chorea and hystero-epilepsy, one of brain tumor with epileptiform convulsions, one of hysteria, and one of progressive paralysis. The results were as follows: In both cases of exophthalmic goitre the protrusion of the eyes disappeared and the goitre diminished in size: the tachycardia diminished in one and persisted in the other. In the three cases of epilepsy improvement was noted during the five months that followed operation: in none did the convulsions recur and in but one infrequent and transitory attacks of vertigo took place. In the other cases no special effect was observed. As a result of the experiences gained in these cases Jonnesco concludes that total bilateral resection of the cervical sympathetic may be practised without secondary evil results. The operation, while not easy, is worthy of trial. In cases of exophthalmic goitre, whose symptoms are largely referable to the cervical sympathetic, resection is an absolute indication, even if supplemented by ligation of the vertebral artery. In cases of epilepsy both physiologic experiments and observation in a case of hemicraniotomy demonstrate a disturbance of the cere-

bral circulation in conjunction with the attack. The results thus far secured justify further trial of the operation.

The Relationship Between Tetany and Rachitis.—In an endeavor to determine the nature of tetany, and especially its relationship with rachitis and laryngospasm, Cassel (*Deutsche medicinische Wochenschrift*, January 28, 1897, p. 69) has made an analytic study of 6,822 cases that came under observation in his outpatient service for the treatment of diseases of children at Berlin. Among this number a diagnosis of tetany was made in 60 cases—in 37 boys and 23 girls, all infants between the ages of four weeks and nine months, the majority being less than two and a half months old. Six were exclusively breast fed; 6 received partly breast milk and partly a mixture of cow's milk and amylaceous food; the remaining 48 received cow's milk and a variety of other food. The state of the nutrition was good in 14, moderately good in 13, poor in 23, and atrophic in 10. All presented spontaneous intermittent spasm, which could also be induced by pressure upon the large nerves and vessels of the affected member; in all but 3 the facial phenomenon (shock-like contraction of the facial muscles on tapping the facial nerve) was present; frequently there was also increased irritability of other muscles. Only 2 of the 60 exhibited laryngospasm and both of these presented also craniotabes, in addition to other symptoms of rachitis. Convulsions were noted in four cases, also in children with rachitis or with craniotabes. Without exception the children were nervous and irritable and their sleep was disturbed. Fourteen exhibited fever, in 9 as a result of complicating conditions, in the remainder without obvious cause. The outcome of the disease could not be learned in 36; of the remaining 24 recovery ensued in 17 and death in 7. In 21 cases digestive disturbances immediately preceded or appeared simultaneously with the tetany: in 5 there was chronic dyspepsia of long standing; in 4 the disease was attended with digestive disorders; in 6 there was obstinate constipation with meteorism; and in 4 there occurred habitual vomiting. In no case was albumin found in the urine; occasionally indican was found. Rachitis was present in 52 of the 60 cases, 82.6 per cent.; in the majority only in slight degree. In 8 there was no trace of rachitis on careful scrutiny. Cases of tetany were seen throughout the entire year, although the largest numbers appeared to occur in spring and the late autumn. The distribution was as follows: In March, 10; in December, 9; in June, 7; in January, February, and May, each 6; in April and November, each 5; in August, 4; in July and September, each 1; and in October none. There was no suggestion of epidemic occurrence of the disease, nor was there any close parallelism between the frequency curves of tetany, rachitis, laryngospasm, and craniotabes, although there was some similarity among the curves. Laryngospasm was observed in 116 cases, especially in the spring. Of this number all but 2 were rachitic. Only 2 suffered from tetany and these 2 were rachitic and also presented craniotabes. Of the 116 cases, 30—26 per cent.—presented craniotabes. In the way of treatment phosphorus had no objective influence upon the rachitis, although it exerted a favorable influence upon the attacks of laryngospasm in two-thirds of the cases. Also on tetany the drug appeared to have no effect. The best treatment of this condition was found to consist in prolonged warm baths of a temperature of from 28 –30° C. (82.4° –86° F.), for twenty minutes, morning and evening. In case of restlessness at night a grain or a grain and a half of chloral hydrate were given at intervals of an hour or two. Of course complications received appropriate treatment and attention was given to dietetic and hygienic conditions. The conclusion is reached that tetany is neither a complication of rachitis nor a result of digestive disturbances, but that it is dependent upon unfavorable conditions of living, and especially improper nutrition and vitiated air—conditions similar to those that are responsible for the development of rachitis.

Hereditary Appendicitis.—Dr. Faisans remarked recently that it was evident that certain families presented a veritable predisposition to appendicitis, which was admirably explained, since, as Dieulafoy had shown, it was a question, in these cases, of a veritable appendicular lithiasis depending upon constitutional and hereditary gout. In the majority of the cases which had come under Faisans' observations the appendicitis had presented itself under the relapsing form and had terminated in perforation, with fatal septic peritonitis. He concluded from this that ablation of the appendix was indicated in all cases, even in the most benign, as a preventive measure. Talamon reported the case of a little boy who had had five attacks of pain in the right iliac fossa during a period of three months. Four years before, a little brother had died from perforating appendicitis, and the mother had consulted him on the advisability of a preventive operation. When Talamon had seen the patient during the last attack he had ascertained by deep pressure the presence of a painful spot a little above the Fallopian arch at the lower external part of the right iliac fossa. The abdomen had been slightly distended, but there had been no puffiness or appreciable tumefaction near the appendix. There had been no fever, but the tongue had been somewhat coated. Three days later pressure revealed the presence of more pain in the right iliac fossa. The diagnosis had appeared certain, said Talamon, and an operation had been decided upon. After three weeks of absolute rest in bed the operation had been performed by Jalaguier, who had found the appendix to be of abnormal length and of the size of a large crow quill; it had not been dilated and had not seemed to be inflamed on the outside. Filamentous adhesions had united it at its upper third to the cæcum. On palpation, a small hard body, which moved under the finger, could be felt about two centimetres from its lower extremity. The lumen of the canal had been free, and the mucous membrane had been covered with a small quantity of a yellowish-brown liquid. The foreign body, which had been arrested toward the lower end of the appendix, was a small oval-shaped mass somewhat like a grape seed in size and in appearance. The results of the operation had been perfect, said Talamon; there had been some vomiting for about ten days, which had been due to the chloroform, but at no time had the temperature exceeded 99.1° F. Talamon thought that the following conclusions might be drawn from the foregoing case: 1. That in certain cases relapsing appendicitis might be due to the displacement of a scybalum in the appendix. 2. That, in view of the hereditary appendicular history, the least pain felt in the right iliac fossa should be considered important, and if the pains recurred at short intervals the involvement or the formation of a scybalum in the appendix should be feared, even if palpation did not distinctly reveal the presence of a local tumefaction. 3. That the only means of preventing the graver symptoms, which probably would not fail to manifest themselves, was ablation of the appendix. Talamon stated that in three hundred cases of appendicitis an hereditary influence had been ascertained in forty per cent., and this, he thought, showed that heredity played an important part in the etiology of this disease.—*New York Medical Journal.*

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

New York, February 20, 1897.

VACCINATION AGAINST TYPHOID FEVER.

We have only passed the threshold of the domain of orrhotherapy and are confronted by almost unlimited possibilities. The therapeutic efficacy of the antitoxin of diphtheria appears to be reasonably established, and the testimony is quite strong as to the successful treatment of hydrophobia, tetanus, cholera, and streptococcous infection upon analogous lines. Evidence further is not wanting of activity in other directions. We have made no material advance beyond the experiences of the brothers Klemperer in the antitoxic treatment of pneumonia, and the problem as to the similar treatment of tuberculosis has not been finally solved. On the other hand, considerable progress seems to have been made in the application of the principles of orrhotherapy to the prophylaxis of typhoid fever. Investigation in this latter direction has been stimulated and at the same time facilitated by the discovery of the influence exerted by the blood of persons who are suffering or have recently recovered from one of the infectious diseases upon the specific micro-organisms of the respective disorders, as manifested by their agglutination and precipitation, their loss of motility, and by their final devitalization. One of the most recent contributions to the literature of this very important subject has been made by Wright and Semple (*British Medical Journal*, January 30, 1897, p. 256), professor and assistant professor, respectively, of pathology in the Army Medical School at Netley, England. These investigators describe briefly the method of antityphoid vaccination that they have gradually elaborated in the course of the period of more than a year during which they have prosecuted their inquiry.

The method employed consists in the inoculation of measured quantities of dead but still poisonous typhoid bacilli. Agar cultures of the bacilli that have been kept for twenty-four hours at blood heat are emulsified by the addition of measured quantities of sterile broth. The resulting emulsion is then sucked into sterile and duly calibrated pipettes, the capillary ends of which are sealed in the flame. These capsules are then placed in a beaker of cold water, which is brought up to a temperature of about 60° C. and there kept for five minutes. When the vaccination is to be practised the capsule is first thoroughly shaken in order to distribute the bacteria through the fluid, and the contents are drawn aseptically into a suitable syringe. The injection is made into the flank.

In later experiments a typhoid culture was employed of such a strength that one-fourth of a tube of a twenty-four-hour culture when injected hypodermically constituted a lethal dose for a guinea-pig of from three hundred and fifty to four hundred grams. When small doses (from one-twentieth to one-sixth of a tube) were employed, the symptoms were comparatively slight and passed off in twenty-four hours. The local manifestations consisted in a little circumscribed tenderness; the constitutional manifestations in a subjective feeling of chilliness two or three hours after the inoculation, with a very slight rise of temperature and a little restlessness at night. With larger doses (one-fourth of a tube) the symptoms were more severe and continued for forty-eight hours. The tenderness increased in intensity and extent, and about the site of inoculation a patch of congestion two or three inches in diameter developed. The related lymphatics became reddened and swollen. Fainting, collapse, nausea, and vomiting appeared in the course of three or four hours, followed by anorexia, fever, and disturbed sleep. Each subject received from forty-five to sixty grains of crystalline calcium chloride for the purpose of preventing undue decrease in blood coagulability and œdema.

Having determined that sedimentation of the bacteria is the phenomenon that will best serve as a criterion of the specific power of a serum, observations were made upon eighteen persons, mostly medical officers of the army or Indian medical service or surgeons upon probation. The results of these observations show that the blood of individuals that have submitted to antityphoid inoculation becomes in some measure inimical to the typhoid bacillus, as manifested by immobilization and agglutination. Experiment showed, however, that an individual whose blood possessed this power of sedimentation is not absolutely protected against typhoid fever, although the inference seems warranted that the blood of a vaccinated person will, short of killing the bacilli, exert such a deleterious influence on them as will result in the effectual protection of the individual against typhoid fever, viz., will render him bacteria proof. To account for the fact that typhoid patients who succumb show the specific sedimentation reaction, it is assumed that every infected animal is working its way up to the acquirement of immunity, from the very moment of infection to the time at which its struggle with the disease finally ceases. The degree of immunity that appears late in the disease, *e.g.*, at a time when the examination is made, while it might have been ample at an earlier period, is insufficient to save the patient at this time.

Inasmuch as the vaccinations can be practised without risk and their adequacy can be easily controlled by examinations of the blood, it is suggested that it would be expedient for all those to submit to vaccination who are likely to be frequently exposed to the risk of typhoid infection, *e.g.*, young soldiers going abroad to typhoid-infected districts, nurses in attendance upon typhoid patients, and persons living in a district that is being visited by an epidemic of typhoid.

THE COMING MEETING OF THE BRITISH MEDICAL ASSOCIATION.

The meeting of the British Medical Association in Montreal in August next promises to be, and we trust will be, a most successful affair and one which will be a credit and an encouragement to our Canadian confrères. We in this country cannot but be glad that this historic association has consented to accept the hospitality of its American daughters, and we doubt not the profession in this city and Boston will welcome cordially any of the British delegates who may pass through either place on their way to Montreal. But here, it seems necessary to remind some of our brethren, our participation in the event should rest. This is not, as some of our enthusiastic and hospitably inclined friends are in danger of assuming, a Pan-Anglican medical congress. It is a little family feast of our British cousins, and one to which we should be very careful not to go without a distinct invitation. Some of our readers may recall an experience which they had in 1890. A number of Americans on the way to the Berlin congress thought it would be convenient and pleasant to stop over in England and attend the meeting of the British Medical Association in Birmingham. They did so, but their reception was marked by a frigidity such as only the Englishman can use to resent what he regards as an impertinence, and there were some heartburnings in consequence.

When the news was received that the association would meet this year in America, we remarked, while expressing our pleasure at the decision, that the matter was one in which we had no official concern. This is a point which seems to have been forgotten by some in the United States, for we have heard that many, especially in the West, propose to neglect the meeting of the American Medical Association in Philadelphia, reserving their time and their money for the trip to Montreal. Several of our Canadian contemporaries have hinted as politely as possible that the doctors this side of the line had better stay here, and we may use stronger language than they would and tell our brethren that if they go where they are not invited they may expect a snubbing. Let them take heed to the warning expressed by the *Canada Lancet* in the following:

"Since our last issue we have received from England the exact wording of the resolution of the council of the association, stating who are and who are not eligible to be members and to attend the meetings of the association. This resolution was passed two years ago, and inasmuch as we hear on all sides that very large numbers of our profession in the United States are proposing to attend the Montreal meeting, it may be well again to point out that, however much the local executive desires to welcome American practitioners, its hands are tied. Those visiting Montreal must either be members or invited guests if they are to enjoy the privileges of the meeting, and only British subjects can be members."

There are to be two large and important medical gatherings in the United States this year, namely, the congress of American physicians and surgeons in Washington in May, and the semicentennial meeting of the American Medical Association in Philadelphia in June. These, with the annual or semi-annual meetings of the various State societies, will afford to every man who has anything of importance to say full opportunity of saying it. The Medical Record will present its readers, as usual, with a full report of the scientific work of the Montreal meeting, but we sincerely hope no American will be seen in Montreal at that time who does not go as an official delegate from some society empowered to send him or in response to a personal invitation from some one in authority. It seems necessary to speak thus plainly, because there is evidently a misconception in this country as to the character of the Montreal meeting. We wish it every measure of success, but, as we said before, it is a strictly family party, to which distant cousins are not invited, and from which, if they wish to retain their self-respect, they had better stay away.

THE HEALTH BOARD AND ITS OFFICIAL DIAGNOSIS.

Physicians of this city are sorely puzzled to know just where they stand in relation to the board of health. The question has arisen during the past week, and in a most disagreeable manner for the physician, as to whose diagnosis of a private case of sickness is to stand—that of the physician who is treating the patient or that of the board whose examiners have made a bacteriological examination in connection with it. The instance in point relates to a child presenting the clinical appearances of diphtheria. A tube was inoculated and sent to the board, while at the same time antidiphtheritic remedies were employed. A report was received from the board leaving the matter in doubt and asking for a second culture. This was sent and the same course of treatment was pursued, but now, the child's condition growing more alarming, the physician administered antitoxin, fearing the consequences of delay. The child recovered and the physician ceased his attendance. Some time after this the parent went to the board to secure disinfection and permits for his children to return to school, when he was informed that there had been no diphtheria in his house and that the doctor had made a mistake in diagnosis.

Upon the strength of this information the physician was told that he might consider himself no longer the family physician, and payment of the bill was refused on the ground that he had treated the child for a disease which it did not have.

It seems clear from the statements of the case as we have received them that the board physician overstepped his duties, and, in perhaps a thoughtless manner, did an injustice, not alone to one physician, but to the whole profession. His removal from office will not efface the injury, but may point an example for future conduct to his successors.

When it is a question as between the clinical and the bacteriologic showing—especially that of the board of health unsupported by other examination—

the rule must be that the clinical diagnosis should stand. In any case, too, it would be far better for the continued existence of harmony between physicians and the board that the latter should refrain from expressing diagnostic opinions to the layman, but should confine their communications, as far as possible, to the physician in attendance.

A PROFESSOR WANTED.

THE Vienna correspondent of *The Lancet* sends a bit of gossip, under the caption "Dishonorable Conduct of a Medical Man." We agree with him that it was quite wrong to collect seventy dollars as the "professor's fee," and give the supposed professor only six-sevenths of it, retaining one-seventh for himself.

The fact of introducing to the patient as "professor" the consultant who held no professorship will not, however, appeal seriously to New York physicians as an unpardonable sin. The terms consultant and professor are synonymous in many quarters of the town. Then, too, professors are so numerous here that such a mistake would be hardly possible. Indeed, should a patient here insist upon having a real professor called, as seems to have been the case in the Vienna incident, the gentleman chosen by the attending physician would in all probability have himself appointed to one of the colleges before the consultation rather than lose the case.

News of the Week.

Hospital and Dispensary Abuse. — The president of the County Medical Association has, by request of fifteen members, called a special meeting of the association for Tuesday evening, February 23d, to consider the hospital and dispensary abuse.

The Board of Health and Tuberculosis.—At the coming meeting of the County Medical Association, March 15th, action will be taken on resolutions condemning the board of health for placing tuberculosis on the list of communicable diseases under the control of the board.

The Plague and the Mecca Pilgrims.—During one of the recent sittings of the international sanitary board in Constantinople, Dr. Hagel directed attention to the imminent danger of the spread of the plague by the Mecca pilgrims. He urged that the pilgrimages from India to Mecca should be entirely prohibited this year. The foreign delegates on the board unanimously seconded his proposals, but they were opposed by the Turkish delegates, who declared that the pilgrimages, being a religious observance, must not be subjected to any restrictions. The *Politische Correspondenz* suggests that it is the duty of the English government to forbid the pilgrimages, and that other European States whose Mohammedan subjects are accustomed to take part in the excursions to Mecca should adopt the same course. The Russian government has done what it can in this direction, having forbidden pilgrimages of Moslems to Mecca through Russian territory, and has also forbidden Russian Christians to visit the shrines in the East. Military cordons have been assigned to watch closely the Russian frontiers to prevent the introduction of the plague.

A Quieting Remedy. — A nurse at the Kings County Hospital was recently dismissed by the superintendent, for trying to stifle the outcries of a delirious patient by pressing a pillow over his mouth.

The Red Cross in Cuba.—It is proposed that a Red Cross expedition be sent to Cuba to aid the sick and wounded in both armies. A large donation was recently declined because it was stipulated that it should be used wholly for the relief of the Cubans. The society could not bind itself to aid only those of one side, but we greatly doubt whether it will be permitted by the army of occupation to render any assistance whatever to the insurgents.

Dr. Perry Millard, of St. Paul, Minn., died on February 1st, in the private ward of the Johns Hopkins Hospital, of pernicious anæmia. He had been there for nearly two months, and though at first hopes were entertained of his recovery, he has lately been failing rapidly. Dr. Millard was one of the most prominent members of the profession in the Northwest. He was one of the first promoters of the Association of American Colleges, and he had been for many years dean and professor of surgery in the University of Minnesota. His labors as an educator helped greatly to advance the curriculum of studies in the medical schools of the West.—*Maryland Medical Journal.*

Cocaine has been declining in price very rapidly of late, owing to heavy shipments of the leaves of the Erythroxylon coca plant from Peru and Bolivia. The drug is now quoted at $2.50 an ounce. Only a few weeks ago it was nearly $4 an ounce.

Dr. James P. Mann has been elected clinical professor of orthopædics in the Medico-Chirurgical College of Philadelphia. Dr. Mann was graduated from Jefferson Medical College in 1887, soon afterward becoming resident physician in the Jefferson College Hospital, and since having maintained active relationship with the department of orthopædic surgery. For two years he performed the duties of clinical professor of orthopædics, on account of the illness of Dr. H. A. Wilson, resigning recently because of criticism of his action in sympathizing with the students in opposing a change in fees during the collegiate session.

Philadelphia County Medical Society.—A stated meeting of the Philadelphia County Medical Society was held on February 10th. Dr. F. A. Packard read a paper on "The Signs of Thoracic Aneurism," and exhibited illustrative cases. Dr. T. S. K. Morton demonstrated the following cases: 1. Gunshot wound dividing the right subclavian artery; hæmothorax; location of the bullet by, and dangerous burning from, the *x*-rays. 2. Traumatic rupture of the middle meningeal artery; trephining; removal of a huge clot; ligation of the vessel. 3. Diffuse osteomyelitis of the femur; profound sepsis and large metastatic abscesses of the lung; hip-joint amputation; complete recovery. He reported also a case of double popliteal aneurism, in which successively both femoral arteries were li-

gated; and also a case of penetrating stab wound of the abdomen, with five wounds of the intestine and the mesentery, which were sutured. In both of these two recovery ensued. Dr. Edward Jackson read a paper entitled "The Hospitals, the Doctor, and the Community." Dr. John B. Roberts, president of the Mutual Aid Association of the County Medical Society, offered a resolution for the appointment of a committee of the County Society to confer with the executive committee of the Aid Society, for the purpose of increasing the resources and enlarging the usefulness of the latter.

Report of the State Board of Health.—The State board of health submitted its report for the year 1896 to Governor Black a week ago. During the year 124,600 deaths were reported, making a death rate for the State of 18.50 per 1,000 of population against 18.60 in 1895. There was one death in 54.20 of the population. This has been the average mortality rate for the past ten years. In the eight sanitary districts into which the State is divided the death rate varied from 21.80 in the maritime district, which includes the metropolis, to 13.10 in the sparsely settled Adirondack and northern district. Through the rural central parts of the State a rate of 14.50 prevailed for the year, and in the more populous manufacturing districts from 16.00 to 18.00. Thirty-three per cent. of the deaths were of children under the age of five years. Under the head of infectious diseases there were 19,510 deaths, only three from smallpox, all occurring in or about New York City. Typhoid fever caused 1,600 deaths—less than usual—the highest number being in the southern tier and Hudson Valley districts, and the lowest, as usual, in the maritime district. Diphtheria caused fewer deaths than during the past ten years—4,600. Scarlet fever caused 771 deaths, the average number of deaths annually for the ten years preceding being 1,600. Measles was more than usually prevalent, but chiefly in the eastern part of the State. The total reported mortality from this cause was 1,617. Whooping-cough caused about 1,000 deaths. Diarrhœal diseases caused nearly half of the zymotic mortality. There were 8,764 deaths from them, and the pretty uniform annual average is about 9,000 deaths. In July nearly one-fourth of the reported mortality was from this cause, and 7,400 of the deaths occurred in the months of June, July, August, and September. The maritime district is by far the largest contributor to the death rate from this cause. Pulmonary tuberculosis caused 13,257 deaths during the year, a greater number of deaths than occurred from any other single cause. The largest relative mortality was in the maritime district. Acute respiratory diseases, which include pneumonia, bronchitis, and other acute affections of the respiratory organs, caused 17,106 deaths, a number below the average for the past seven years.

Commission of Charities.—Hospitals under the charge of the charities commission are to be improved at an expenditure of a million of dollars. Among the improvements promised are six new pavilions for the almshouse, an enlargement and increase in the number of pavilions for the insane department at Bellevue; a new hospital in the Harlem district, probably to be located at Madison Avenue and One hundred and thirty-fifth Street; and two new contagious wards for Randall's Island.

City Hospital.—According to the present plans of the commissioners it is stated that much needed improvements are to be made at the City Hospital at an expenditure of about $100,000. The kitchen is to be placed in the dome. The distance of the kitchen from the wards has been one of the serious objections to the present arrangement.

Hospital Extortion.—Charges of certain irregularities at the Gouverneur Hospital are being investigated by the commissioners of charities. It seems scarcely credible that an ambulance surgeon could be guilty of extorting money from the poor for services which the city provides. So far it would seem that no evidence of such misconduct has been brought forth.

Obituary Notes.—Dr. Henry Hartshorne, of Philadelphia, died in Tokio, Japan, on February 10th, at the age of seventy-three years. Six years ago Dr. Hartshorne went on a tour of Japan. He remained a couple of years, and formed a liking for the country. Returning to the United States, he consented two years ago to return to labor in connection with the missions of the Society of Friends. Dr. Hartshorne was graduated from Haverford College in 1834, and took his degree in medicine at the University of Pennsylvania six years later. He was elected professor of the institutes of medicine in the Philadelphia College of Medicine in 1853, and in 1859 was chosen as professor of the practice of medicine in the University of Pennsylvania. He became professor of hygiene in the latter institution in 1866, and in 1867 succeeded to the chair of organic science and philosophy in Haverford College. He also held professorships in the Pennsylvania College of Dental Surgery, Girard College, and Woman's Medical College, all of Philadelphia. He was the first person to ascertain by experiments on himself and others, in 1848, the safety and effects of the internal use of chloroform. He was also the author of a number of medical works.—Dr. Edwin A. Bourgoin, of Paris, died on February 10th, at the age of sixty years. He was professor of chemistry at the School of Pharmacy, and attained some prominence a number of years ago on account of his opposition to Pasteur and his teachings.—Dr. Philip H. Fuller died in Brooklyn on February 12th, at the age of thirty-five years. He formerly practised medicine in Vermont, and removed to Brooklyn only a few months ago.—Dr. A. Van Nest Baldwin died in New Brunswick, N. J., February 14th, after a two weeks' illness with pneumonia. He was a son of Dr. Henry R. Baldwin, a prominent physician of New Jersey, and was born in New Brunswick, November 16, 1858. In 1879 he was graduated from Rutgers College, and from the College of Physicians and Surgeons in this city, in 1882. At the time of his death he was secretary of the board of health and sanitary inspector, and was serving his second term as a member of the board of education. A wife and an infant daughter survive him.

Addition to a Municipal Hospital.—An annex to the diphtheria pavilion and an administration building for the Municipal Hospital of Philadelphia have just been completed, and were opened for inspection on January 21st. The new pavilion contains two wards, each forty feet long by twenty-five feet wide, and four private rooms, two of which are thirteen by thirteen feet, and separated from the wards by a wide vestibule, which opens upon a large porch, twenty-five feet long, enclosed in glass, which may be removed in the summer season. At one end of the new pavilion are a porch and corridor, nine feet wide and thirty-eight and one-half feet long, connecting the pavilion with the administration building, which separates the large and small pavilions. The space between each pavilion and the administration building is twelve feet long by nine feet wide, and is enclosed in glass, which can be removed when desired. The new pavilion is supplied with air drawn from a stack some fifty feet from the building, and conveyed underground through a tunnel to a chamber where it is heated by steam coils and then propelled by a fan into the wards and private rooms. The foul air is driven out of the apartments by a fan operated by an electric motor.

Unsanitary Bakeries.—At a meeting of the Woman's Health Protective Association of Philadelphia, on January 26th, a report from a committee previously appointed to investigate the sanitary condition of bakeries stated that in many instances these are located in cellars, are unventilated, and often are so near to outbuildings that the contents of the latter ooze through the walls and trickle into the shop: sewers frequently become choked, and their contents are sent back into places where the bread is made that is sold in the store above. In some places the men wore scarcely enough clothes to cover them. As a rule, no air shaft or other means of ventilation is provided, and the odor in many places is extremely offensive. The hours of labor were seven days in the week, and from fourteen to twenty-four hours a day. Dr. William H. Ford, president of the board of health, stated that a bill is being prepared for presentation to the legislature, prohibiting work on Sunday, as well as the employment of persons suffering from transmissible diseases, together with provision for other sanitary measures.

The Ohio State Medical Society will hold its fifty-second annual meeting in Cleveland on May 19, 20, and 21, 1897. The president of the society is Dr. F. C. Larimore, of Mount Vernon; the secretary, Dr. Thomas Hubbard, of Toledo.

The Connecticut Humane Society.—According to the annual report, recently issued, this society relieved during the past year 1,150 persons and 3,522 animals. During the year it received $52,197, including a legacy of $42,487 from Anna F. Brown, of Quincy, Ill., and has now invested funds of $42,171.

Caveat Pransor.—The Supreme Court of Illinois has decided that a restaurant keeper is not responsible for the quality of the food which he serves (*Journal of the American Medical Association*). If he fails to exercise ordinary care in the furnishing of food to his patrons, or conducts his business in a careless or negligent manner, and damage results, he is liable therefor. But as to food served at a restaurant, such as oysters, ice cream, and the like, the court says that it is not aware that there ever existed a rule establishing liability similar to the one which makes innkeepers presumptively liable for losses which happen to the goods of their guests.

Legislation Concerning Nursing-Bottles. — The municipal authorities of Buffalo, at the urgent request of the health officer, Dr. Wende, recently passed an ordinance forbidding the sale of nursing-bottles with tubes, because of the difficulty of keeping them clean.

The Gouverneur Hospital.—The plans for the new Gouverneur Hospital, which have recently been adopted, call for a four-story brick and terra cotta building with limestone trimmings. The structure, which will be in the form of an L, will extend one hundred and sixteen feet along Water Street and one hundred and thirty-seven along a street not yet opened. The first floor will contain the offices, the toilet rooms, and a spare room. The second and third floors will contain, besides the wards, the dining-room and sleeping-rooms for nurses and attendants. The laundry, kitchen, store room, and operating-room will be on the top floor. The building will cost about $200,000.

A Nun Doctor.—According to the *Catholic Standard and Times*, Sister Raphael, M.D., a member of the religious order of the Sisters of St. Joseph, is a practising physician in Kalamazoo, Mich. The same journal states that one of the inmates of the Gray Nuns' Convent in Montreal is a regularly qualified dentist.

British Medical Ethics.—As a corollary to the discussion that has been going on in this journal and elsewhere, a correspondent sends us the following newspaper cutting relative to "the Adelaide Hospital squabble": "The select committee appointed to inquire into the management of the Adelaide Hospital sat again this evening, and Dr. Cecil Corbin was cross-examined by the chief secretary. The witness referred to a certain operation, and said he was disgusted with the treatment of Dr. Napier. He was asked by the chief secretary why, when he saw what he thought was a glaring blunder being performed by Dr. Napier, and knowing a patient's life was in danger, he did not interfere. He replied that, in the interests of the greatest number, he hoped to see the man die on the operating-table, so that Dr. Napier's reputation might be damned."—*The Medical Press.*

Money in Twins.—Plural births have not usually been looked upon with favor in the popular mind, but this may be changed, if a new scheme recently announced is found to be all it claims to be. The *British Medical Journal* says that there is now an insurance company in London which undertakes to insure the risk of twins. Every subscriber of one shilling is promised £6; of two shillings, £12; of three shillings, £18; and so on up to £30 for five shillings.

It is added that the insurance must be completed one calendar month before accouchement, but the subscription insures for eight months from the day of application. This generous offer, a correspondent writes, deserves publicity. The average frequency of twins is about one in eighty, so that this new and invaluable system of insurance offers odds of one hundred and twenty to one against an event, the actual odds in fact against this event being only eighty to one. Further, if the pregnant woman happens to consult her doctor during the seventh or eighth month of pregnancy, he may be able to ascertain with certainty the presence of twins, and enable his patient to get odds of one hundred and twenty to one against a certainty. It may be, although the advertisement does not say so, that the money is paid only on the birth of living twins. The mortality of twin births has, we believe, never been very exactly worked out, but is generally reckoned at between ten and fifteen per cent., so that the difference of the odds in favor of the patient would be less by this extent.

Increase of Medical Students in Ten Years.—In 1883–84 the number of regular schools of medicine in the United States was 88; in 1893–94 it was 109. Homœopathic schools in 1883–84, 13; in 1893–94, 19; and eclectic, 9 in 1883–84, and 9 in 1893–94. The number of students increased in this period from 10,600 to 17,601.

An Insane Family.—In Skibbereen, Ireland, recently, two brothers and three sisters, all living in the same house, suddenly developed acute mania. No cause for the outbreak could be discovered.

Political Appointments to Hospitals.—Chicago suffers, like New York, from the patronage of doctors by politicians. The *Chicago Medical Recorder* says that the annual disturbance between the medical profession and the county commissioners is now on in that city. Seventy-five men have been appointed to the advisory staff of the county hospital, three being appointed by each commissioner. The size of the staff and the manner in which appointments are made have robbed the position of all honor, dignity, and desirability.

Chicago Surgeons are Overworked, if the reports of their movements, published from time to time in the journals, are correct. The *Texas Medical News* says that Dr. Senn is in Texas, he having been ordered South by his physician to recover his health, which has become impaired as a result of professional overwork. The *Fort Wayne Medical Journal-Magazine* announces that Dr. J. B. Murphy has recently sailed for Europe, where he goes in the interest of his health, which, under the severe strain of professional work, has become impaired.

Eye Infection through Borrowed Spectacles.—It is stated in the *Journal of the American Medical Association* that it has for some time been a growing custom for ophthalmologists and opticians to lend London-smoked or other tinted coquille spectacles to patients under mydriasis. The spectacles are returned after the passing of the mydriasis and are again lent to other patients. The editor says that he has known of cases of infection not readily explainable except as due to the wearing of glasses that others have used. We trust this custom will not spread, for it is a dirty and, in these days of asepsis, a most reprehensible practice.

The Tuberculosis Commission in Connecticut.—There has been dissatisfaction among the dairymen and farmers in Connecticut in regard to the use of tuberculin in the diagnosis of disease in cattle, and a few days ago a resolution was introduced in the legislature suspending all powers and duties of the tuberculosis commissioners until the committee on agriculture can prepare a new bill.

The Berlin Congress, which meets this year from June 9th to 14th, will have as general questions of discussion, chronic articular rheumatism, epilepsy, and Basedow's disease.

Reducing Fees.—It is regarded as undignified, if not unprofessional, for a medical consultant in the West End of London to accept any fee less than a guinea. The result of this is that the younger men get nothing, and all the guineas go to those of established reputation and fame. It is now proposed, however, to recognize as strictly professional the acceptance of reduced fees, even as low as seven shillings, or $1.75.

Greek Medical Women.—Even in the beginning of the present century the Greek ladies whom Byron admired were obliged to walk veiled, after Asiatic fashion, through the streets of Athens, and they were not allowed their due share in the intellectual culture of the renascent Hellas. It is interesting to learn that a few days ago two young Athenian ladies, the sisters Angelica and Alexandra Panagiotatos, passed their medical examination with brilliant success, and each received her diploma as doctor. The elder is aged twenty-two, the younger twenty. They are natives of Corfu, where they made their first studies, continuing them later in the French school at Athens. They matriculated afterward at the University of Athens.—*The Westminster Gazette.*

The Notification of Consumption.—If the effectiveness of compulsory measures for the prevention of the spread of consumption were plain and indisputable, and, therefore, did not meet with decided objections on the part of many members of the medical profession, the protective compulsory measures adopted by the New York board of health and recommended by the St. Louis board of health might be admissible, even if the chances of recovery of many consumptives would thereby be jeopardized. The fact, however, is that men thoroughly acquainted with the known biologic characteristics of the tubercle bacillus consider the contemplated compulsory measures inadequate and unnecessary. It is to be hoped, therefore, that in this respect St. Louis may not follow into the footsteps of New York, and we firmly believe, moreover, that the medical profession of New York will, after due consideration, not indorse the action of the board, and that the new measure will have but an ephemeral existence.—*Medical Review.*

Reviews and Notices.

SYSTEM OF DISEASES OF THE EYE. By American, British, Dutch, French, German, and Spanish Authors. Edited by WILLIAM F. NORRIS, A.M., M.D., and CHARLES A. OLIVER, A.M., M.D., of Philadelphia, Pa. Volume I., Embryology, Anatomy, and Physiology of the Eye, with 23 Full-page Plates and 362 Text Illustrations. Philadelphia: J. B. Lippincott Company. 1896.

IT has evidently been the design of the editors and publishers of this work to spare no effort or cost to make it as complete as possible. In their stated endeavor to produce a system of diseases of the eye which at this time will compare favorably with the "Handbuch" of Graefe Saemisch at the time of its publication they have set a high mark, which they will attain if the excellence of the present volume is manifested in the volumes that are to follow. The names of the distinguished contributors are a sufficient guarantee of the high quality of the work contained in Volume I., which comprises six hundred and seventy pages, printed in large type and profusely illustrated.

The article on the development of the eye was contributed by the late John A. Rider, Ph.D. Although admirable in many respects, it does not express the latest views regarding the development of some of the parts of the eye: for example, the capsule of the lens, the posterior portion of the cornea, and the suspensory ligament of the lens. The statements regarding the capsule of the lens and the posterior portion of the cornea are corrected in the article on the microscopical anatomy of the eye, but the views regarding the suspensory ligament of the lens, as advocated by E. Treacher Collins and Schoen, which are now quite generally accepted, are here rejected for those of older writers. The contribution by Thos. Dwight, M.D., LL.D., "The Anatomy of the Orbit and the Appendages of the Eye," contains much of value; however, some small omissions are noticeable and the original illustrations are not up to the excellence of those that have been embodied from other works. The part devoted to a description of the anatomy of the eyeball and of the intra-orbital portion of the optic nerve, contributed by Frank Baker, M.D., Ph.D., comprises one hundred and eight pages and is very elaborate. Extensive discussions of disputed points are included and a large bibliography is appended. An exceedingly interesting chapter is that by George A. Pearsal on the microscopical anatomy of the eyeball, particularly because of the full discussion of the recent great advances in the views regarding the formation of the retina, due to the work of Cajal, Dogiel, and others. Except in regard to the suspensory ligament, the views expressed in this paper are fully up to date. The editors are to be congratulated on securing so valuable a contribution to the work. The anatomy of the intracranial portion of the visual apparatus is fully and well treated by Alex. Hills, A.M., M.D. This is followed by an article on congenital malformations, which completes the consideration of the tissues of the eye contained in this volume. The chapter on the dioptrics of the eye is clear, concise, accurate, and not too much encumbered with formulas. Articles devoted to the consideration of light, binocular vision, normal color perception, and the photo-chemistry of the retina, all admirable in their way, complete the volume.

When a number of monographs on kindred subjects are embodied in a work it is scarcely possible to avoid some overlapping of statements, some of which may conflict; in the volume under review but little of this exists, and what there is is not conspicuous.

DISEASES OF THE EYE. A Handbook of Ophthalmic Practice for Students and Practitioners. By G. E. DE SCHWEINITZ, A.M., M.D., Professor of Ophthalmology in the Jefferson Medical College, etc., etc. With 256 Illustrations and Chromo-Lithographic Plates. Second Edition, Thoroughly Revised. Philadelphia: W. B. Saunders. 1896.

THE work is comprised in a single royal octavo volume of six-hundred and seventy-four pages. It is printed on heavy paper and the type is of good size and clean cut. Some of the illustrations are of little value, but as a whole they are very good. As stated in the preface, the work is particularly adapted for the student and practitioner who desire to begin the study of ophthalmology. This is more manifest in the chapters devoted to diseases of the eye than in those devoted to optical principles and physiological optics. These chapters, which are excellently written by Dr. Jas. Wallace and revised by Dr. E. Jackson, are sufficiently comprehensive to merit perusal by the practising ophthalmologist. An exhaustive exposition of ophthalmology cannot be comprised within the pages of such a volume. This has been fully realized by the author, who has eliminated as much discussion of the subjects considered as is possible without impairing the value of the work. Short, concise descriptions of diseases, their causes, symptoms, treatment, etc., sufficiently separated and classified to be easily grasped, has been the rule. The advice given in the chapter on refraction and on the treatment of diseases is well chosen and perfectly safe to follow. The meagre remarks on pathology are fully justified by the scope of the work. Short but valuable chapters are found which treat of the adjustment of spectacles, the use of Javal's ophthalmometer, and of Stevens' tropometer.

MANUAL OF DISEASES OF THE EAR, INCLUDING THOSE OF THE NOSE AND THROAT IN RELATION TO THE EAR. For the Use of Students and Practitioners of Medicine. By Thomas Barr, M.D., Lecturer on Diseases of the Ear, Glasgow University, Senior Surgeon to Glasgow Hospital for Diseases of the Ear, etc., etc. Second Edition, with 229 Illustrations. New York: The Macmillan Company. 1896.

THIS work is comprised in an octavo volume of four hundred and fifteen pages. The type for the greater part is sufficiently large, but some minor portions are printed in smaller type which is somewhat trying to the eyes. The illustrations are good and well chosen. The manual is designed for the use of students and practitioners, and it is certainly admirably adapted for this purpose. Separate chapters are devoted to symptomatology, causes of ear diseases, and methods of treatment, apart from the consideration of these topics accompanying the discussion of the individual diseases. This plan usually necessitates repetition, but in the way the subjects are treated by the author of this work there is little repetition and much has been gained in clearness by the manner of association. An appendix, devoted to the consideration of otalgia and a few pages of formulas, is found. A few pages at the back are devoted to a full general index, an index of authors, and an extensive bibliography. It is seldom that a work so compact, so complete, and so masterfully written, on any subject in medicine, is offered to the student and practitioner.

THE CELL IN DEVELOPMENT AND INHERITANCE. By EDMUND B. WILSON, Ph.D., Professor of Invertebrate Zoology, Columbia University. 364 pages. New York: The Macmillan Company. 1896.

THIS work is the fourth in the Columbia University series, and an elaboration of a course of lectures given at Columbia University several years ago. It is a *résumé* and critical digest of the work done on the lines of cellular investigation during the last few years, in which a number of investigators have invaded the African regions of the ultimate elements of the organic structures, to find there a wide geographical territory as yet unexplored and unnamed. These Stanleys of cellular science overwhelm the student who has no tkept pace with these histological researches, not so much by what has already been determined as by the great possibilities of future discoveries. The hypotheses of to-day will form stepping-stones to the new hypotheses of to-morrow. It is hoped that it will be possible to worry out of the ultimate protoplasm and its ultimate nucleus, the hidden and ever-evading secret of life itself and the transmission of physical inheritance. According to these researches, the cell, which we have been accustomed to regard as the ultimate element, may be "a congeries of self-propagating units of a lower order."

The reader will turn with eager interest to see what Professor Wilson and his authorities have to say in regard to the relation of the cell to heredity. Inheritance, he says, is the recurrence in successive generations, of like forms of metabolism. The nucleus alone suffices for the inheritance of specific possibilities of development. It is also an organ of metabolism, and so concerned in the process of construction, the egg cytoplasm being the result of nuclear activity dependent upon the nucleus for development

The writer confesses that one is unable to explain development and inheritance, beyond referring this power to the in-

herent organization of the germ. He expresses a hope that the splendid achievements of cell research in the past twenty years stand as a promise of its possibilities for the future, and that step by step the way may yet be opened to an understanding of these problems, inheritance and development.

The book is well written, well printed, well illustrated, and will be welcomed by biologists, whether agreeing with the conclusions reached or not, as comprehensively reviewing and bringing together at the present time the researches on cell structure and development upon which so much work has been done in the last five years.

ROENTGEN RAYS AND PHENOMENA OF THE ANODE AND CATHODE. Principles, Applications, and Theories. By EDWARD P. THOMPSON, M.E., E.E. Concluding Chapter by PROF. WILLIAM A. ANTHONY. 60 Diagrams. 45 Half-tones. New York: D. Van Nostrand Company.

IN this work the principles and practical application of the Roentgen rays are fully and clearly explained, as also "the phenomena occurring between and around charged electrodes, separated by different gaseous media at various pressures. The specific aim is the treatment of the radiant energy developed within and from a discharge tube, the only source of *x*-rays." The book is profusely illustrated with pictures of apparatus and of skiagraphs. It also contains a photograph of Professor Roentgen and a picture of the physical institute of the University of Würzburg, where Roentgen lives, lectures, and conducts his experiments.

FOOD IN HEALTH AND DISEASE. By I. BURNEY YEO, M.D., F.R.C.P., Examiner in Medicine at the Royal College of Physicians; Professor of Clinical Therapeutics in King's College, London, and Physician to King's College Hospital; Author of a "Manual of Medical Treatment," etc. Philadelphia: Lea Brothers & Co.

THIS is a revised edition of Prof. Burney Yeo's work, which appeared first in 1889. The author has taken the opportunity to make a few changes and to add a number of pages in the part devoted to feeding in disease. The subject of the sterilization and pasteurization of milk receives attention in an appendix. All who are acquainted with Dr. Yeo's excellent work, and there are few to whom it is not known at least by reputation, will welcome the appearance of a new edition.

PRACTICAL DIAGNOSIS: The Use of Symptoms in the Diagnosis of Disease. By HOBART AMORY HARE, M.D., B.Sc., Professor of Therapeutics in Jefferson Medical College of Philadelphia; Physician to the Jefferson Medical College Hospital, etc. Philadelphia: Lea Brothers & Co. 1896.

IN this book the author takes up the various symptoms located in parts of the body or organs, such as paralysis or spasms in the hands or feet, hemiplegia, headache, vomiting, cough, pain, and the like, and discusses the conditions which may give rise to these manifestations. This plan is greatly to be preferred to that usually followed, in which the symptoms of a special disease are grouped together under that head. In the old method the reader was obliged to know the disease, or at least to guess at it, before he could verify his diagnosis by means of the description in the book before him. By Hare's method, on the contrary, the physician takes the symptoms which he sees and, using them as catch words, hunts up the disease in the treatise. The latter serves, therefore, as an index of disease. The plan is rational and the author's execution of it is good.

VETERINARY HOMŒOPATHY IN ITS APPLICATION TO THE HORSE: Including a Code of Common Suggestive Symptoms. By JOHN SUTCLIFFE HURNDALL, Member of the Royal College of Veterinary Surgeons, England. Philadelphia: Boericke & Tafel. 1896.

THE terms employed in the descriptions of the varied diseases to which the horse is liable have been chosen, the author says in his preface, so as not to confuse a layman; hence this work can be utilized by all who desire to combat these affections by homœopathic remedies and are deprived of veterinary skill. The author says that the blood of a horse supposed to have died of anthrax may be rubbed into a cut on a rabbit's ear to determine the matter, but aside from this he strongly opposes vivisection or this class of experiments. "There is no proof," he says, "that the millions of animals which have been cruelly tortured and sacrificed to the whims of fanciful scientists have ever produced the slightest benefit to science, inasmuch as the results obtained from such experiments have never saved a single life." Recognizing the strength of this language and boldness of expression, he believes it "capable of distinct proof." The chapter on "Diseases of the Ear" is like that of the celebrated one on the "Snakes of Ireland." It occupies four lines, but they are of interest and importance: "We have never in the course of our experience come across a disease of the ear in the horse, and, with the exception of occasional injuries, there would appear to be nothing calling for special treatment in the organs of hearing among the equine race."

A list of prominent suggestive symptoms is a useful feature of the work, added as an appendix, and a good index will help out the lay reader.

LA BICYCLETTE. By DR. JUST LUCAS-CHAMPIONNIÈRE, Honorary President of the "Touring Club de France." Paris: Léon Chailley.

THIS is an address in favor of bicycle exercise.

EINLEITUNG IN DEN CURSUS DER DERMATOLOGIE. By DR. A. POLOTEBNOFF, O. Professor in St. Petersburg. Berlin: Aug. Hirschwald. 1896.

A BROCHURE of forty-seven pages of excellent print, being an address delivered at the opening of the dispensary for syphilis and skin diseases at the Marien-Krankenhaus.

THE MEDICAL NEWS VISITING LIST. Record of Practice for Thirty Patients per Week. 1897. Philadelphia: Lea Brothers and Company. 1896.

THIS year's record of practice contains much that is of value to the busy practitioner, such as "Therapeutic Reminders," "Examination of the Urine," "Table of Eruptive Fevers," "Important Incompatibles," "Poisons and Their Antidotes," etc. It is arranged for thirty patients a week, bound in leather, not too bulky, and has a thumb index for its various departments.

OM DE PAPILLÆRE OVARIAL-KYSTOMER. Af OSCAR SEMB. Kristiania: Steenske Bogtrykkeri. 1896.

A BROCHURE of about one hundred pages upon the papillomatous cysts of the ovary, with a few illustrations.

OPHTHALMIC OPERATIONS AS PRACTISED ON ANIMALS' EYES. By CLARENCE A. VEASEY, A.M., M.D., Adjunct Professor of Diseases of the Eye, Philadelphia Polyclinic. With 56 illustrations. Published by the Edwards and Dock Company. 1896.

THIS work purports to be an aid to the student of ophthalmology in performing operations on animals' eyes, with a view to fitting the individual for general ophthalmic operative work. In a limited way the volume is of value; however, it is extremely elementary and not sufficiently minute in description to advance the student to any great degree. Such works cannot supplant the instruction that may be obtained by the student who takes an operative course in the surgery of the eye upon the cadaver and upon the eyes of inferior animals under the immediate supervision of a competent instructor.

Hyperchlorhydria in Early Life.—1. Hyperchlorhydria may be observed in quite young infants. It is rare in nurslings, but seems relatively more frequent in those weaned prematurely and put upon an inappropriate diet. 2. Clinically it is not revealed by any differential sign which may distinguish it from the other forms of dyspepsia of early life. 3. Chemically it is revealed by the presence of free hydrochloric acid, which normally is wanting in youthful age, and also by an acidity which is at times marked. 4. From a therapeutic point of view hyperchlorhydria interferes with caseification, which takes place again when the excess of hydrochloric acid is neutralized by alkalies.—ODDO *and* DE LUNA, *Revue de Thér.*

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, February 4, 1897.

JOSEPH D. BRYANT, M.D., AFTERWARD E. G. JANEWAY, M.D., IN THE CHAIR.

Valedictory Address by the Retiring President.—DR. JOSEPH D. BRYANT, on retiring from the presidential chair, which he had occupied the past two years, reviewed the business affairs of the academy. That which now gave the academy its greatest lustre was its library. The interest taken in this was manifest from the fact that within the few months since the special committee had been appointed to secure a hundred-thousand-dollar endowment fund, a very considerable proportion of this amount, one-half, would be at the academy's command as soon as it should secure additional subscriptions to the amount of twenty thousand. Surely the immediate use of this sum was an object worth working for. The number of volumes in the library was forty-six thousand, of which ten thousand were duplicates. There were six hundred and eighty medical journals, representing the medical achievement and thought of twelve different nations. By advertising the binding of journals, etc., it was thought that from thirty to fifty per cent. could be saved on the stationery bill. It was intended to improve the heating and ventilation of the building: to print the corrected by-laws and rules: to take steps, if possible, toward paying off the remaining indebtedness of the academy, $10,000. The resident membership was eight hundred and seventy. All doctors in honorable standing, having the welfare of the profession and of the academy at heart, were invited to join it. Every one must appreciate the foresight of Dr. Loomis, in donating a sum to be devoted to increasing the good fellowship of the academy. Mention was made of the successful and pleasing celebration of the academy's semicentennial. Dr. Bryant then introduced his successor, Dr. Janeway.

Inaugural Address by the President-Elect.—DR. EDWARD G. JANEWAY, president-elect, said he had hesitated to become a candidate for the office, feeling that there were others in the profession who deserved the honor by reason of greater scientific attainment, seniority, and ability to promote the interests of the academy. But when he was assured that his election was likely to be unanimous, the interpretation was forced upon his mind that it was the purpose of the members to work in harmony with him for the further upbuilding of the organization of the academy, its influence for the good of the public health, and advance of s ientific medicine. From this point of view he had not felt himself at liberty to decline the high honor, but to accept it with sincere thanks, and with it the laborious duties which it implied.

In the course of his address Dr. Janeway suggested as a new field of effort the establishing of a laboratory department as a workshop for the members, and mentioned the necessity for completing the endowment fund of $100,000 for the library.

Referring to the achievements of American medicine, he mentioned the names of Wells, Jackson, Simpson of Edinburgh, and Morton in connection with anæsthesia, and expressed the opinion that Morton deserved special honor for demonstrating that it was possible to do surgical operations without inflicting pain. Further, he said, let us to-night do honor to our associate, Dr. Joseph O'Dwyer, for introducing intubation.

There should be placed upon the walls of the large room of the academy portraits of all of its presidents, and throughout the building portraits of more of the distinguished members of the profession, that their friends might recognize their faces as well as profit by their writings. Among ex-presidents, one missed a painting especially of Dr. Alonzo Clark, and it would be a graceful act of recognition if the profession and medical students should contribute toward procuring a portrait of this unpretentious but most distinguished teacher and practitioner: and also one of the late Dr. Austin Flint. Difference of opinion in regard to medical politics could make none inappreciative of the scientific merit of the departed. Among other ex-presidents whose portraits were wanting were Dr. John T. Metcalf, who was still living: and Drs. Cox and Alfred C. Post.

In reply to the question what could the academy do during the next two years in its own interest and that of the public, the president suggested that a committee be appointed to consider the question of the best method of presenting medical expert testimony in courts, and report its conclusions in a paper before the academy.

It was often said that reforms should begin at home. Dr. Janeway was not sure but what he was himself partly to blame for a condition of things relating to medical colleges and hospitals which ought to be changed. In the past the duration of the course in our medical colleges may have been too short to permit of carrying out the curriculum and allow time for sufficient out-of-door exercise and recreation to maintain reasonable health. Now that the course had been lengthened, the evil should be corrected. The second matter concerned hospitals and hospital internes. The atmosphere of hospitals after a time exerted a depressing influence on those within them, and the older the institution the more hospitalism there was. Under present regulations the number of internes was too small to enable them to do the work in the hospitals properly, without breaking down or injuring their health under the excessive strain. Yet there were many competitors for every position, and the rejected candidates not infrequently were as well qualified for the places as those who were appointed but who happened to pass a somewhat better examination on the questions propounded. It would seem that some plan might be devised which would enable a larger number of graduates and undergradates to obtain coveted hospital experience, and thus also relieve, at least in a degree, the overworked internes. A committee might be appointed, composed, if it were desired, entirely of college and hospital men, to suggest some practical method for bringing about the needed change.

The recent munificent gift of a million dollars to an existing hospital institution in this city deserved mention, and the president doubted not that he expressed the sentiments of the members in thanking the donor for his gift. The multiplication of new institutions was to be deplored; the upbuilding of the old was to be praised.

The president hoped that during the term of his office the remaining debt of the academy, $10,000, would be paid off. Personally he disliked debts, and desired to see institutions in which he might be interested freed therefrom, in order that new aspirations might arise to stimulate effort.

Portrait of Dr. J. W. Schmidt.—DR. LEWIS A. SAYRE presented, in the name of the donor, Mrs. James E. Andrews, an oil portrait of her father, one of the founders of the academy, Dr. John W. Schmidt. Dr. Schmidt was born in South Carolina in 1811, was graduated from the Geneva Medical College about 1830, and died in 1858, at the age of forty-six. He was a friend of Dr. Mott, and was one of the first surgeons in the city during his time.

Dr. Samuel S. Purple presented the diploma of Dr. Schmidt, granted by the Geneva Medical College, which, he said, had on its faculty during the four years of its existence more distinguished men than any similar institution in this country. A more disgraceful piece of legislation was never enacted than when this college was enacted out of existence.

Portrait of Dr. Alfred L. Loomis.—Dr. William M. Polk presented, in the name of the family of the deceased, an oil portrait of the late president of the academy, Dr. Alfred L. Loomis. Dr. Loomis, he said, was one of the strong men of the profession. He came to the city a friendless boy, almost from the outset was threatened with tuberculosis, yet he threw himself into the midst of the turmoil incident to metropolitan life, and step by step advanced to positions of highest professional eminence. If there was one thing above another which characterized him it was that he knew what he wanted, and, knowing it, he had courage to work for it. He had concentration, which enabled him for the time to lose sight of all side issues and throw his full energies into the work before him. He had said to the speaker on one occasion: "You waste too much time in side issues. Devote yourself wholly to that which will lead to your professional success. If you prepare a paper, let it be upon the dearest professional wish which you have in mind. If you speak upon any subject, if you think upon any subject, let it be all in that direction." And thus it could almost be said that even while he slept he kept himself in touch with the thing which was dearest to him—his professional success. When Dr. Loomis began to interest himself in the affairs of the academy, it was at a time when the code issue was thrown upon it. All remembered the part which he took in that controversy, and he took it because he felt that the very life of the academy depended upon the issue being in the direction of liberality. Under such honest, noble, broad lines, this organization had developed as he had wished it, until it had become the mouthpiece of the profession in matters concerning the public health as well as all related to medical science.

Dr. Fordyce Barker.—A tablet to accompany the portrait of Dr. Fordyce Barker was presented by Mrs. Barker.

On motion of Dr. A. Jacobi, a vote of thanks was extended the several donors for their generous and valued gifts.

The academy then went into executive session.

Special Meeting, February 11, 1897.

Edward G. Janeway, M.D., President, in the Chair.

Traumatic Neurasthenia and Hysteria.—The meeting was arranged by the section on neurology, Dr. Pearce Bailey, chairman. The paper with the above title was read by Dr. Philip Coombs Knapp, of Boston. It would be seen that he had limited his paper to two of the commoner and more definite types of nervous trouble of apparently functional nature following traumatism, but in considering only traumatic neurasthenia and hysteria he did not mean to imply that other neuroses could not have such an origin.

The paper was based on an analysis of two hundred cases of traumatic neurasthenia and hysteria in the hospitals of Boston. Of these, one hundred and three were not, so far as he knew, subjects of litigation. Of the other ninety-seven, most of them were sent him for the purpose of getting his opinion for use in court. He had rarely been consulted in any litigation cases for injury involving one or more peripheral nerves, and seldom for injury pointing definitely to spinal disease. The explanation was hard to make, for cases of spinal injury and injury of peripheral nerves were not infrequent in hospitals. Possibly in litigation cases of this class the symptoms were so definite that they were settled in or out of court without consulting specialists. The author differed from Strümpell, who claimed that the genesis of most of the trouble in the litigation cases was psychical, the questions which constantly worried the patient's mind being: "Shall I get damages? How much shall I get? Shall I be able to work afterward?" Notwithstanding the malevolent psychical influences attending these cases—the desire for gain, the desire for putting the best foot forward, the gloomy prognostications heard on the witness stand—he could not accept Strumpell's view for reasons, some of which follow: 1. Under conditions precisely similar one saw the symptoms of traumatic hysteria or traumatic neurasthenia in non-litigation cases, in which the factors referred to were absent. 2. The symptoms developed almost immediately after the accident in many litigation cases, before these factors could have acted. No doubt, however, factors connected with litigation aggravated the symptoms somewhat. Further, the relative frequency of the symptoms in the litigation and the non-litigation cases was about the same. In other words, he could find no symptoms in the one class of cases not present in the other and which would warrant the term litigation hysteria or litigation neurasthenia. In many, but not all of the litigation cases, the patients had worried about the lawsuit; but in the non-litigation cases the patients had also been disposed to worry, though about something else.

Dr. Knapp thought Strümpell had given insufficient weight to the physical influence and too much to the psychical. He classified the two hundred cases according to the nature of the injury, the symptoms, etc. The injuries took place from railway accidents, getting on or off tramways, getting in or out of carriages, etc. In but few instances were bones broken. On the whole, the circumstances attending the two classes of cases, litigation and non-litigation, did not differ greatly, and since the symptoms were very similar, the conclusion was drawn that the desire for gain in the one class played only an insignificant part in the genesis of the trouble.

The author stated that psychical shock alone might produce hysteria or neurasthenia, but it was more difficult to answer the question whether physical injury alone, unattended by psychical shock, could do so. His own belief was that psychical shock played a subordinate part, and that physical injury was the important cause. Neuropathogenic heredity, upon which the French laid stress, he had found of minor importance. He was able to obtain a neurotic history in eight cases of hysteria, in seven of neurasthenia, and in a few there was a history of previous ill health.

Dr. Knapp then spoke of the symptoms, and said that traumatic hysteria and traumatic neurasthenia had many symptoms in common, the boundary line not being in all instances very clear. Among symptoms mentioned were inability to work mentally or physically, headache, vertigo, pain in the back and limbs, paræsthesia, rapid pulse, loss of appetite, diminution of urine, exaggerated reflexes, congestions, coldness of extremities, etc. The differential points between neurasthenia and hysteria were mentioned, particularly those relating to contraction of the visual field, hemianæsthesia or local anæsthesia, and disturbances of special senses of a nature usually regarded as diagnostic of hysteria. While attaching weight to these evidences of hysteria, the author did not regard them as always diagnostic. For instance, in four of the cases of neurasthenia there was contraction of the visual field, without other stigmata of hysteria. But the ma-

jority of cases which presented cutaneous anæsthesia and contraction of the visual field were cases of hysteria.

Regarding the prognosis, there had been difficulty in following up cases to determine the ultimate result. In 28 cases of hysteria, 18 of them were litigation cases, 10 non-litigation cases. In the former, 1 patient recovered completely, 5 patients improved considerably, 7 very little, 5 died. Of the 5 that died, 1 died of unknown cause, 1 had improved considerably but died of intercurrent pneumonia and delirium tremens, 1 steadily grew worse and died of a low form of pneumonia, 2 grew worse and died in exhaustion. It would seem from Dr. Knapp's observations that the remarkable recoveries which one heard of taking place as soon as damages were obtained did not appear. A number of cases had continued six to twelve years; they might improve, but still present some distinct symptoms. There seemed to be no direct connection between the intensity of the hysteria and the gravity of the prognosis. The longer the hysteria lasted, the less likelihood of complete recovery. Some cases of neurasthenia progressed more favorably under treatment than hysteria, and, on the whole, he thought the prognosis was more favorable. But he had seen some cases of eight, twelve, and even twenty years' duration.

The author then touched upon treatment. He thought some occupation was to be preferred to allowing these patients to brood over their troubles while doing nothing, yet judgment was required, lest they do too much or worry under the labor and anxiety of making a living. These people were apt to be looked upon as extortionists, but facts showed that the accusation was unjust. A considerable number of them never recovered their health, and the amount received in damages was, in the author's experience, inadequate, especially if the expenses of litigation were deducted. In thirty cases the average damages had been about $5,500; at least half was used in litigation, and very few cases came to trial before two years, some not for ten years. The law ought to be amended to hasten the court proceedings, as delay added to the gravity of the prognosis. It was best to urge prompt settlement out of court, whenever it could be done without too great sacrifice.

How to Avoid Litigation Cases.—Dr. M. Allen Starr opened the discussion. He would give a few of the points in the fourteen cases of traumatic neuroses (including both the hysteria and the neurasthenia cases under that term) which had come under his observation during the past two years. He did not see many of these cases, because when asked to examine them it was usually with the expectation on the part of the patient or the corporation that he would be biassed toward that side, and he refused. The first effort on the part of the physician should be a correct diagnosis, more especially in determining whether the case were one of organic lesion or of functional disturbance. As a rule, the prognosis would be more serious in the former. Three of Dr. Starr's cases were in foot-ball players; the trauma was received while they were playing football; the symptoms of neurasthenia following the accident were marked and had not disappeared in from two to five years, and in none of the three was there a question of suit for damages.

Regarding the symptoms, the pain was likely to be referred to the point of the original injury, as the back or head, and not to a distant part which received its innervation from the seat of the trauma. The reverse was the case in organic lesions. This was an important differential symptom between the two classes of cases. Among the symptoms in the order of frequency in traumatic neuroses were intense headache, tenderness along the spine, general weakness, fatigue on effort, insomnia, frightful dreams, palpitation of the heart, morbid fears, numbness or tingling on one side of the body, tremor, increase of knee jerks, some irritability of the bladder. In none were there objective signs of paralysis or complete anæsthesia, there was no loss of control of bladder or rectum. In but two cases was there any question of damages, and therefore that element could be excluded in etiology and duration of the symptoms. He was quite convinced that cases which developed traumatic neuroses were cases predisposed to neuroses before the injury, just as was true of occupation neuroses. Hysterical anæsthesia had a different distribution from anæsthesia of organic disease. The perineum and genitals were spared, and there was absence of paralysis of rectum and bladder.

Litigation More Injurious than Trauma.—Dr. Charles L. Dana said that ten years ago, perhaps five years ago, he would have agreed entirely with the conclusions of the author, but the last few years the tide of litigation had risen, and seemed more frequently to play an important part in what was known as traumatic neuroses—traumatic hysteria, traumatic neurasthenia, or a mixture of the two, or some other neuroses. While he believed these people were often wronged through the delays of the law, still he refused to take part in any given case until he had made a thorough examination into the symptoms and history, in order to determine how far the affection was genuine. The question was mainly one of diagnosis. He did not think it was so hard to distinguish between a functional disease which was real and an organic disease, as it was to distinguish in functional disorders how much was simulation or exaggeration. A great many of these people were really hurt and were neurasthenic, but many of them were not very badly hurt, and under the excitement and anxiety of litigation their symptoms were intensely increased, not only increased, but they finally became real, so that the patients became as much injured through the psychical effect of litigation as they were through the original injury, if not more. We saw some distressing cases of delays, obstinacy, and cruelty on the part of corporations.

A case was more apt to be genuine in the old or in the young, under eighteen years. Dr Dana thought females were less likely to simulate in these cases than men, although usually they might exaggerate a little. He was more suspicious of men. Traumatic neurosis was unlikely to occur in a man of steady habits, never known before to be nervous. But the diagnosis would have finally to rest on the objective symptoms of hysteria and neurasthenia. He had the absolute conviction that hemianæsthesia, limitation of the visual field, and involvement of special senses all on the same side were pathognomonic of hysteria. He had certainly seen twenty cases of that type, in which the symptoms had finally disappeared. One important point in differentiating between the anæsthesiæ of hysteria and of organic disease of the cord was the fact that in the former there was an uneven sliding away into the normal area of the anæsthesia to pain, temperature, and touch, whereas in organic cases the boundary line was sharper.

Dr. Bernard Sachs agreed with the author in the main, yet he thought there were some pure and some mixed litigation cases, and we should counteract that tendency as much as possible. While we should have feeling for the injured, we should search for the exact truth. He believed the better part of the medical profession, like the better part of the legal profession, tried to prevent litigation when fair settlement could be made out of court. He objected to the term traumatic neurosis. If the word were used at all, it should be in the pleural—neuroses. Many cases should be put down as traumatic hypochondriasis. While he agreed as to the importance of the sensory test, he thought it had been overstated. Hysterical conditions following injury were often more serious in

preventing earning a living than some minor organic lesions.

Dr. Frederic Peterson thought that in the same way as we made classifications of functional cases into hysteria, neurasthenia, hypochondriasis, etc., without traumatic history, the same divisions could be made in traumatic cases. In litigation cases care was necessary, for in many there was exaggeration of the symptoms, and personally he had seen a good many cases of simulation.

Evolution of Names.—Dr. J. Arthur Booth observed successive steps of advancement in the use and dropping of such terms as spinal concussion, brain concussion, railway spine, railway brain, traumatic neurosis, and the present subdivisions into traumatic hysteria, traumatic neurasthenia, and their combinations. As to narrowing of the visual fields in hysteria, it was found less frequently than on the other continent. He believed simulation and malingering were rare, but that exaggeration was frequent.

A Family of Simulators.—Dr. Pearce Bailey related the history of a family by the name of Freeman, three or more members of which, including mother and two daughters, had brought numerous fraudulent lawsuits for alleged accidents, usually in railway or tram cars, in Chicago, Boston, and New York, the past few years. In most instances, even when simulating spinal paralysis involving the lower extremities, bladder, and rectum, they had accepted one hundred or a few hundred dollars as settlement out of court. Finally they had been clearly exposed.

SECTION ON GENERAL SURGERY.

Stated Meeting, February 8, 1897.

W. W. Van Arsdale, M.D., Chairman.

Recto-Urethral Fistula.—Dr. James P. Tuttle presented two men whom he had cured of recto-urethral fistula by operation—a rather rare condition and one generally conceded to be very difficult to heal. The chief interest in the cases was that they had been cured by one operation. In one, however, preliminary inguinal colotomy had been performed. This patient's recto-urethral fistula had existed about four years, and operations performed for its cure by other surgeons before he saw the patient had failed. In the other case the fistula had existed six months. One patient had been presented before the genito-urinary section in December last. The operation was, as far as he knew, novel. The mucous membrane of the rectum on each side of the fistula was dissected back three quarters of an inch; connective tissue was trimmed off; going back into the soft tissues, he dissected off a short flap on each side with which to make a new urethra at the sloughed portion. Having closed the urethra, he sutured the mucous membrane of the rectum over the soft tissues which had been used to repair the urethra. The lower end of the urethra was not closed, but was carried forward in order to make thorough perineal drainage of the pocket. Thus the case took the course of an ordinary perineal section. In one a catheter passed through the urethra was kept in the bladder for three weeks; in the other only twenty-four hours.

Enormous Hernia Cured by Bassini's Operation.—Dr. George E. Brewer presented a man whom he had cured of the largest inguinal hernia that he had ever seen treated by the Bassini method. The hernia extended to the knees, was nearly two feet in circumference, contained eleven feet of intestine and about two pounds of omentum. Seven inches of the intestine were firmly adherent to the bottom of the sac. Hemorrhage was severe, and it was necessary to fold up in towels and apply hot salt solution for two hours before returning to the abdomen. The patient was told that the operation would probably result only in improvement, not cure, but sixteen months had elapsed without any sign of recurrence.

Removal of Large Bony Callus Following Fracture of Clavicle, for Relief of Paralysis; Cure.—Dr. Brewer presented a man who two months ago had come to the hospital with the most marked deformity following fracture of the clavicle that he had ever seen. A large callus had formed at the angular junction of the fragments and had involved the brachial plexus, producing partial arm paralysis. Only after the man had signed a written statement that he would not hold the surgeon or the hospital responsible for the result did he consent to operate. He removed the bony callus, then brought the divided ends of the clavicle—separated by a space of at least an inch—together with wire. The paralysis disappeared, and the result was in every way successful, although the clavicle on that side was shorter than its fellow by more than an inch.

Further Observations on Fracture of the Neck of the Femur in Childhood.—Dr. Royal Whitman presented two patients and read the paper. He also presented illustrative anatomical specimens and skiagraphs. In 1890 he had first presented a case of fracture of the neck of the femur in a child, four others in 1892, and since then he had seen five more cases. The accidents, which had caused certain symptoms, had been of a nature that might produce this fracture, and in 1890 the diagnosis of fracture of the neck of the femur was made largely by exclusion, but to-day could be confirmed by skiagraph. In nearly all instances the patients were brought by the parents with the supposition that they were suffering from hip-joint disease. The subject was not yet considered in the text-books separate from the same accident in adults. The author considered the subject under four heads: 1, the immediate diagnosis and effects; 2, differential diagnosis from hip disease during recovery; 3, diagnosis between fracture and epiphyseal separation; 4, the remote effects of fracture.

The difference between the early and the remote effects of fracture of the neck of the femur in childhood was well illustrated in the two cases presented. In the one of injury from a fall of some feet about a year ago there was still scarcely any deformity; only slight elevation of the trochanter on the affected side, slight shortening, slight eversion of the leg, slight inclination of the body toward that side. There had been no treatment. The shortening did not exceed half an inch. The other child, now aged seven, had sustained a fall from the fourth story about four years ago. There was little effect on the leg at first; only slight pain and limping. Since a month later the child was still limping somewhat and had a little pain, it was brought to the hospital, where the diagnosis of fracture of the neck of the femur was made. To-day the case illustrated the important point brought out in the paper, namely, that fracture of the neck of the femur in childhood caused the neck to assume a more nearly horizontal line, weakened it, and in this position it sagged more readily than in the normal oblique position under the weight of the body. As months and years passed, the trochanter continued to rise in relation to the head of the femur, there were shortening and limp, the nutrition of the limb suffered, and it became smaller relatively to the other leg. It was the future effects of the fracture which led him to suggest treatment with a view to breaking up the partial impaction and restoring the upward direction of the neck, which was the natural protection of the bone from injury. Dr. Whitman thought fracture of the

neck of the femur in childhood occurred more frequently than was supposed, because of failure to recognize the true nature of the injury.

Anomaly of the Femoral Artery.—Dr. Brewer showed an anatomical specimen lent him by Professor Huntington, of the College of Physicians and Surgeons, in which there was very great enlargement of the sciatic artery, taking the place of the femoral in that limb, the femoral in the other limb being present and of normal size. There were only about ten cases on record of a similar anomaly.

Operative Surgery at the City Hospital, with a Completed Report on the Study of Wound Infection.—Drs. George E. Brewer and Philip H. Hiss were the authors of the paper. Dr. Brewer was the reader. During the first period of Dr. Brewer's work at the City Hospital there was want of a modern operating-room, and this fact and faulty operative technique led to wound infection in practically every case. They set to work to correct this condition of things, and had gradually worked up to the point where they had two properly equipped operating-rooms and had adopted a technique which during the latter part of 1896 had given results which compared favorably with those of other hospitals. The present report contained a summary of 109 operations: 9 on the head, 11 on the trunk, 7 on the thorax, 8 on the abdomen, 20 on the ischio-rectal region, 8 inguinal, 20 on the upper extremity, 30 on the lower extremity. Of the 109 patients 87 were discharged cured; 9 died. Of the 9 deaths only 1 could be fairly attributed to the operation—an osteo-plastic operation upon the skull for epilepsy.

The paper described the technique, particularly the antiseptic and aseptic technique, carried out during the three or four periods into which the cases were separated. The improvement had been gradual, but finally to a great extent satisfactory, and the elaborate technique had been adopted on account of the unusual difficulties of securing non-suppurative healing in this particular hospital among this particular class of patients. Many of the patients were syphilitic, were in depressed general condition, and had led unclean lives. Dr. Hiss had made a bacteriological study of the operative technique and of the air and dust of the operating-room with a view to perfecting the results of treatment. Among the facts brought out was that while the operating-room was modern there was open communication with the wards, through which a draught set in from the wards toward the operating-room. A study of the dust from pans of a given area and some minutes' exposure in the air of the operating-room showed by culture test some germs and moulds. This had led Dr. Brewer to keep trays containing instruments and dressings under a small canopy stretched over a wire framework, one side flap hanging free to permit of ready access to the instruments. Bacteriologists had shown that it was impossible to render the hands of the surgeon or the skin of the patient entirely sterile. For this reason all assistants were required to wear rubber gloves which could be rendered sterile, so that the operator's hands alone came in contact with the wound. For sterilizing the operator's hands and the patient's skin they had adopted practically the Fürbringer method, which included much scrubbing and the use of alcohol and carbolic acid. Of the last forty-three cases ninety-one per cent. had run a perfectly aseptic course.

Dr. Hiss made some verbal remarks, in which he stated that the stopcock of the steam sterilizer should not be turned immediately if one would get the full effect of high temperature under pressure.

Dr. Dawbarn did not think there was much danger of contamination through the air. He liked the Fürbringer method of preparing the hands, because it did not hurt them. The patient's skin should be treated for twenty-four hours, a wet antiseptic cloth being left on during that time.

Dr. Wiggins, one of the surgeons of the City Hospital, said they were much handicapped by the fact that the staff rotated every six weeks. Dr. Brewer was to be congratulated on his good results.

Dr. Coley thought this second paper by Dr. Brewer showed that the question which arose during the discussion on his former one, whether the patient's condition had to do with the development of sepsis, must be answered in the negative. In his hernia operations he allowed no hand to touch the wound except his own, and he obtained primary aseptic union in ninety-six per cent. of the cases. This was in an amphitheatre where pus cases were constantly being operated upon by Dr. Gibney.

Dr. Gallant called attention to the fact that Lister in his recent address had given up all his former ideas regarding infection taking place through the air, and had come to believe that infection nearly always took place from the hands and dressings. Dr. Gallant allowed only one assistant to touch instruments. During his early training in hospitals he had observed the antiseptic technique of many surgeons; it had varied in the hands of each, and the one who had obtained the best results was he who gave particular attention to asepsis and scarcely any to antisepsis—using only green soap, alcohol, and water. Dr. Gallant looked upon the exudate of serum in the wound as an excellent pabulum for bacteria. By using a dressing which absorbed that and by keeping the edges of the wound together, sepsis was avoided and primary union resulted. The castor-oil dressing, to which he had referred at a recent meeting, fulfilled that purpose. He did not have stitch-hole abscesses, not even in septic cases in tenement-house surroundings.

Dr. George Woolsey referred to the investigations of certain German surgeons, which showed that in some cases in which there was absence of bacteria in a section of skin removed from the edge of the wound sepsis occurred, while in some others in which bacteria were found primary non-suppurative union occurred. This showed that the presence of bacteria in the skin did not signify that there would necessarily be sepsis or want of primary union. Staphylococci were found in some of the cases. Dr. Woolsey thought the stitches used in closing the skin should be superficial ones. During four months' service at Bellevue last winter he had had but one case of infection.

Dr. R. A. Sands thought that on analyzing the Fürbringer method scrubbing seemed to be its main characteristic. He had no doubt that the removal of germs was due largely to the mechanical act of scrubbing, and that bichloride and alcohol acted a very small part. Bichloride, 1–1,000 or 1–500, had little power of sterilizing the hands, as he had himself demonstrated. It hurt the hands. The permanganate and oxalic method required a number of dishes, ten minutes' time, and cut the hands; it was impractical. Lawson Tait relied mainly on mechanical means for cleansing, and Dr. Sands had not the slightest doubt that the basis of his success was scrubbing with sterilized water.

Dr. Howard Lilienthal said germs were in every open wound, still we should do all we could to secure asepsis. The surgeon must show mechanical ingenuity to close wounds if possible, but if space were left he should drain.

Cancer of the Breast.—Dr. Torek presented a cancer of the breast removed by the radical method from a woman who first noticed the tumor five years ago.

SECTION ON GENITO-URINARY SURGERY.

Stated Meeting, February 9, 1897.

RAMON GUITÉRAS, M.D., CHAIRMAN.

Fibroid Sclerosis of the Corpora Cavernosa.—DR. R. W. TAYLOR presented a patient illustrating this condition, and read a paper containing the histories of a number of others. He thought the term fibroid sclerosis was more appropriate than the older one of chronic circumscribed inflammation of the corpora cavernosa, for there were no evidences of inflammation connected with it. While it had long before been described by Peroni, Kirby, and others, the subject had not been in very presentable shape until Keyes read his paper in 1874. A great deal had been added since that time. After presenting one patient and giving brief histories of four others seen by him since May, 1896, an unusually large number in so short a time, the author described the condition as it usually presented itself clinically. The minute pathology of the condition had been little studied. The patient seldom consulted the surgeon until the condition had advanced to the point of deforming the penis on erection. The presence of the fibroid sclerosis or plate of fibroid tissue after a time interfered with uniform congestion of the organ, permitting of erection in one part, of partial flaccidity in another, and causing curving which interfered with or prevented coitus. The plaque, one or more, nearly always began at the median line, might involve one or both corpora cavernosa, very rarely the corpus spongiosum; exceptionally the morbid process extended downward into the trabeculæ; it might attain a length of two inches, but he had never seen the whole length of the organ involved; the feel was very dense, but usually somewhat elastic, not bony. The form was usually saddleback. He had seen only two or three cases in which the plate was unilateral, and in them the penis when erect had a lateral bend. There was no case on record in which the sclerosis had disappeared. As the patients were usually over forty-five years of age and the sexual powers were on the decline, they bore their inability with fortitude. It caused no pain. There was no particular treatment. The diagnosis was from syphilitic tumors and perhaps carcinoma. In gummata, of course, treatment promised more. The cause of fibroid sclerosis was unknown. Diabetes played no part in the author's experience. In several cases there was no venereal history, no history of trauma.

Was It Carcinoma?—DR. SAMUEL ALEXANDER related a case which was treated at Bellevue in 1894. He supposed it was one of fibroid sclerosis, since all the points in the case corresponded with the description given by Dr. Taylor and others. The tumor was on the dorsum of the penis, was movable, elastic but hard, of saddle shape, about three and a half by two and a half centimetres, with a thickness of one and a half centimetres. It caused the penis to bend up during erection. He told the man no harm was likely to result from removing it, although he could promise no benefit. He was anxious to get the specimen, and with the man's consent removed the tumor. It had been examined by three pathologists in Carnegie laboratory, all of whom were inclined to the opinion that it was carcinoma of the corpus cavernosum, although there were some evidences of epithelioma. As far as Dr. Alexander was informed, carcinoma of this part was very rare.

DRS. KLOTZ, LADOWSKI, GUITÉRAS, and others made some remarks or gave some experience with fibroid sclerosis of the corpora cavernosa. Dr. Goldenberg, of the University laboratory, was of opinion that the specimen under the microscope of supposed carcinoma of the corpora cavernosa presented by Dr. Alexander was not carcinoma nor epithelioma, but fibroid degeneration. He asked for a section that he might study it more carefully, and Dr. Taylor hoped a section would also be sent the laboratory of the College of Physicians and Surgeons, since the case was an important one and, as it stood, might be supposed to throw some doubt upon the clinical diagnosis of fibroid sclerosis of the corpora cavernosa as heretofore made.

Mycosis Fungoides.—DR. LADOWSKI presented a man illustrating the rare skin affection called mycosis fungoides. When presented, the numerous circular spots over the body were of chocolate color. In the successive several attacks they had commenced as itching; then there was a red eruption, followed by fever and weakness; the spots later coincided and changed to brown color. There was no history of malaria, syphilis, or kidney disease.

Kollmann's Urethral Dilator and Urethroscopic Tube.—DR. FERD. .C. VALENTINE, in presenting Kollmann's urethral dilator and also his urethroscopic tube, referred briefly to the development and perfection of instruments for dilatation and irrigation treatment of urethritis, and said that those who had followed this treatment appreciated the fact that humanity was indebted to Oberländer and more recently to Kollmann for its introduction.

DR. J. P. TUTTLE thought one instrument served the purpose for nearly every part of the urethra.

DR. GUITÉRAS thought the Oberländer dilator was the most ingenious dilator ever invented, and furnished the best method for dilating the urethra.

THE NEW YORK PATHOLOGICAL SOCIETY.

Stated Meeting, November 25, 1896.

JOHN SLADE ELY, M.D., PRESIDENT.

Bacillus Aerogenes Capsulatus.—DR. JAMES EWING presented specimens from a fatal case of placenta prævia, occurring at the Sloane Maternity Hospital. Accouchement forcé had been done for a median placenta prævia, and immediately after the operation, and again two hours later, a considerable quantity of salt solution had been infused. The subject died four hours after delivery, apparently from acute anæmia and shock. The autopsy was made within fifteen hours after death. There were no signs of cadaveric decomposition, but the anæmia was extreme. There was an entire absence of rigor mortis. In the region of the uterus, on the right side, was a considerable extravasation of blood in the broad ligament, and the tissues in this region were very emphysematous. There was a smaller degree of emphysema on the left side. The spleen was enveloped in what appeared to be a loose membrane, but which proved later to be its capsule, which had been distended by the gas or air found in the region of the right broad ligament. The capsule was almost stripped off from the spleen. The surface of the liver showed a considerable number of small air vesicles. On section, there was distinct crepitation. The kidneys showed slight acute degeneration, and in a few places these same air vesicles or blebs. On opening the heart it was noted that no air escaped, and no lesions were found except just below the aortic valves, where the endocardium was slightly stripped from the myocardium by exceedingly minute air blebs. The vessels in the neighborhood of the uterus were slit up as far as the inferior vena cava. All of these vessels contained frothy blood. The vessels in the neighborhood of the site of the injection were free from air. The cause of death was undoubtedly the acute anæmia. The chief point of interest was the development of this quantity of gas in the

course of a very few hours. From the quantity of air present, it seemed as if air embolus could be fairly excluded, and that the condition was probably due to the bacillus aerogenes capsulatus. Dr. Norris had succeeded in isolating this bacillus, and growing it.

The speaker said that this subject was now exciting considerable attention. It had been admirably condensed in an article by Dr. Welch in the first number of the *Journal of Experimental Medicine*. Welch had first published the observations on this bacillus in the *Johns Hopkins Hospital Bulletin* for 1893, but Fraenkel, independently of Welch, had identified a similar bacillus as the cause of malignant œdema. Welch stated that the bacillus had been undoubtedly seen again and again before he discovered and isolated it, but he had found no record of such a discovery. In 1889 Dr. R. G. Freeman had presented to this society a case in which the bacteriological examination had been made by Dr. Prudden. The growth had been attempted on gelatin, but had proved negative. In sections of the liver which were distended with these air blebs he had found large masses of a bacillus corresponding with the description given by Welch. It was not known at that time that the bacillus was anaerobic. Not long after the publication of the articles of Welch and Fraenkel, it was shown that this germ could be found during life, as well as post mortem. Fraenkel, in 1893, isolated it from gaseous phlegmon, and about this time a case had been reported in which a patient died of acute septicæmia after an abortion, and all the tissues had been found extremely emphysematous. From this case a pure culture had been obtained of the bacillus aerogenes capsulatus. Welch had seen several cases of bullet wounds and railroad crushing injuries, in which in from sixteen to twenty-four hours after the injury the patient had been affected with the usual symptoms of septicæmia, but they were associated with the development of gas. These cases had usually proved fatal. He mentioned six cases of gaseous phlegmon, one of fibro-purulent peritonitis due to rupture of an ovarian cyst, two of peritonitis due to rupture of typhoid ulcers, and two of pneumo-peritonitis from typhoid fever, without rupture of the intestine, thus indicating that the bacillus could travel through the unbroken peritoneum. Another case, reported by Welch, followed a strangulated hernia; and another a hemorrhagic infarction of the intestine. It had been found in pleurisy when there was no possibility of infection from without, and it had been known to follow infarction of the lung, and to occur in one case after pneumonia. These cases showed that the bacillus in question had a very wide distribution, and might, therefore, complicate any ordinary case of septicæmia.

Dr. Charles Norris presented a number of culture tubes showing the growth of the bacillus aerogenes capsulatus, and also exhibited under the microscope a smear made from the liver. One of the cultures had been made on an agar plate in an atmosphere of hydrogen for three days. It exhibited the typical colony, with the branching processes from the borders.

The President said that these were the first cultures of this germ that had been made in this city. He asked if there were any association of this germ with the subcutaneous emphysema sometimes noticed —a condition often transitory. The condition was apparently not inflammatory. He recalled seeing in Bellevue Hospital such a case. In this case there was a sudden development in an individual of an emphysema, appearing first in the groin and abdomen, and then extending down nearly to the knee. After about twenty-four hours it disappeared, without having given the patient any special inconvenience.

Dr. Ewing replied that he had never seen such a case. The introduction of this bacillus into the human system was always marked by fever and other pronounced constitutional disturbances. He desired to emphasize the fact that the three cases observed at the laboratory of the College of Physicians and Surgeons had been in connection with parturition and operations on the uterus. In two of these there had been very severe hemorrhage. The growth of the germ is extremely rapid, for when the liver was removed it contained only a few vesicles, yet within one hour the air vesicles were large and very numerous. The medico-legal bearing of this subject should be mentioned. Welch had called attention to the importance of making a bacteriological examination to determine the presence or absence of this bacillus in cases of supposed air embolus. Air embolus had always stood as a diagnosis in medico-legal works, yet Welch thought it probable that many of these cases had been really infections with the bacillus aerogenes capsulatus.

Chondroma of the Finger.—Dr. J. S. Ely presented two tumors of the hand. The first one presented was a chondroma removed from the left little finger at the metacarpo-phalangeal articulation. The patient, a man twenty-three years of age, had noticed a small lump about ten years prior to the removal of the tumor, at the right metacarpo-phalangeal articulation. Similar tumors developed at all of the joints of the little finger and ring finger of the right hand, and at the left metacarpo-phalangeal joint on the left hand—in other words, the tumor presented was the last one to develop. These tumors were quite large, but were painless, and did not interfere with the movements of the fingers. He would consent only to the removal of the tumor on the left hand This tumor measured about three by two and one-half centimetres. The section presented showed the typical structure of a chondroma. This structure was interesting, as illustrating the extreme lawlessness of tumor growths in general

Recurrent Giant-Cell Sarcoma of the Hand.— Dr. Ely then exhibited a recurrent giant-cell sarcoma of the hand. He said that on January 1, 1896, Dr. Dawbarn had brought to him a tumor for examination, which had been removed from a man of twenty-five years. The specimen was the fourth finger of the left hand, the third and fourth metacarpal bones and surrounding tissues, and a small tumor situated at the end of the third metacarpal bone in the tissues between it and the base of the fourth finger. The tumor was spheroidal, and measured three by three by two centimetres. It was quite freely movable and rather hard. No attachment to adjacent metacarpal bones could be made out. On section it was fleshy in appearance, lobulated, and rather sharply circumscribed. This tumor was a recurrent growth, the third finger having been removed about six months before. Microscopical examination of the recurrent tumor showed it to consist for the most part of spindle cells, closely packed together and lying in the meshes of a fine reticulum of fibres, scattered through which were many giant cells of variable size and shape. There was no sign of degenerative change in any part of the tumor. The first tumor removed was a finger greatly enlarged and almost destroyed at its base. From a study of this last specimen he thought there was but little doubt that the giant-cell sarcoma originated in the proximal phalanx of the finger, and probably from its periosteum. A rather interesting feature in this case was that there was absolutely no involvement of the skin. The tumor had grown from the remnant left at the first operation. The healing of the wound was perfect, and there was no subsequent breaking down of the cicatrix, as was so often the case with recurrent sarcomata. Ziegler considered the hand the most frequent site of chondromata in general. An examination of

the recurrent tumor seemed to indicate that there was no liability of its recurrence again unless there had been a metastasis prior to this last operation. He did not consider such a tumor very malignant.

Dr. Ewing recalled a tumor of similar appearance in a similar situation. It had been removed in a not very radical manner, and there had been a recurrence in a short time. Just before a second operation had been contemplated, the tumor had begun to disappear, and had ultimately been entirely absorbed. There had been no further recurrence. He would like to ask Dr. Ely if he considered these giant cells to be derived from the osteoclasts.

Dr. Ely replied in the affirmative. He said that if a tumor were not sharply circumscribed, one was justified in attributing to it a more malignant character than to a distinctly encapsulated tumor like the one just presented. Even in the worst cases, giant-cell sarcoma was not so malignant as a melano-sarcoma. He thought that giant-cell sarcomata were quite frequently encapsulated. These tumors usually destroyed bone very rapidly, yet he did not recall ever having seen a distinct metastasis from a giant-cell sarcoma.

The society then adjourned.

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

PROPOSED HOSPITAL BOARD—GODSON ON ANTISEPTIC MIDWIFERY—ACTION FOR ALLEGED NEGLIGENCE—SORE THROAT OR DIPHTHERIA?—LORD LISTER AT BELFAST.

London, January 29, 1897.

The proposal to establish a central hospital board for London was discussed at a meeting summoned for the purpose on Monday last by the Charity Organization Society or rather by its council. Medical men were invited by post cards, and a large number attended, as several leaders were announced to speak on the occasion. There seems little doubt that a considerable number of people is impressed with the idea that some centralization is desirable for the purpose of preventing hospital abuses. But then the different institutions have diverse interests, and, though overlapping might be prevented, it is not easy to see how responsible managers are to be superseded or restrained. The Charity Organization Society is certainly not the body to which many would willingly submit. Indeed I doubt if it has done any good hitherto. Its *raison d'être* seems to be to provide a comfortable post for its one chief official, and to cultivate the art of interfering with other people's affairs. Certainly it makes inquiries at times and reports to subscribers on individual applications for help. But this plan of charity by deputy is not likely to commend itself to the really charitable. To return to the meeting. It was presided over by Lord Stamford, who pointed out that the hospitals were founded for the benefit of the suffering poor, though other interests have arisen in connection with them, and that there exists a general feeling that the present state of things is not just what ought to be.

Sir William Broadbent moved a resolution in favor of a central board on a representative basis, and appointing a general committee of about one hundred and fifty members with power to add to its number and appoint an executive committee. He said nothing in the meeting was hostile to hospitals and spoke very moderately about acknowledged abuses. He did not deny the good work of the special hospitals which were started, because the larger institutions were too slow in recognizing the necessity of departments which had since been established. This is no doubt true, but by no means the whole truth, and if the scheme for a central board is carried out the smaller hospitals are almost sure to suffer. Even the Sunday fund has caused the greatest dissatisfaction in this respect by its partiality, and there has often been talk of a revolt against its iron-bound rules. But the Sunday fund has no control beyond deciding what charities it will assist and to what extent. The proposal of the Charity Organization Society is more extensive, and might only result in giving its officials better position and better pay. Sir William referred to the rumor that the Prince of Wales might lead the celebration of the Queen's reign by an effort to benefit hospitals. In that case there would be a central board *ad hoc*, and if it gave general satisfaction it might be the commencement of a permanent organization with all the influence of royalty to back it up. Certainly that would be a thousand times better than a committee formed by the self-elected Charity Organization Society. The resolution was seconded by Mr. V. Horsley and two amendments were proposed. These, however, were negatived and the original resolution was carried by a large majority.

Dr. Clement Godson has been fortunate in the choice of a subject for his valedictory address to the Gynecological Society, if one may judge from the full reports and comments he has secured in the several journals. Quoting a recent utterance of Dr. Bantock, a past president of the society, Dr. Godson proceeded to state the experience of the City Lying-in Hospital before and after the antiseptic era. This hospital is one hundred and twenty-four years old, and it was quite a common occurrence for it to be closed on account of puerperal fever, while many thousands of pounds have been sacrificed in structural alterations, sanitary remodelling, demolitions, and rebuildings carried out under the superintendence of the best scientific advice. All efforts had, however, failed to bring about more than temporary reduction of the mortality prior to the introduction of antiseptics. Since then puerperal fever has become, in the words of Dr. Cullingworth, a preventable disease. Dr. Godson has given long service to the hospital, and could therefore speak from painful experience succeeded by a happier time. In 1870 drainage and other renovation reduced for a time the frightful mortality of 1 in 19. In 1877 it was necessary to close the hospital again and £4,500 was spent. After sixteen months' closure the mortality was reduced to 1 in the first 278 cases admitted, but by 1880 the old figure of 1 in 19 had again been reached. Closure followed and a further outlay of £1,000. The same process was repeated again and again with similar results. In 1886 the use of corrosive sublimate was begun, and from July of that year to September, 1887, 480 women were delivered in the hospital without a single death. During the last ten and a half years out of 4,608 deliveries there were only 11 deaths—a mortality of 1 in 419. In the five years from January 1, 1892, to December 31, 1896, there were 2,892 deliveries with 3 deaths, and these 3 not due to septic infection but 2 to eclampsia and the other to embolism. These statistics only confirm those of Dr. Boxall, Dr. Cullingworth, and Sir J. Williams. Dr. Godson was able to state that in not a single instance had there been the slightest symptom of mercurial poisoning, so that fear may be dismissed as far as midwifery is concerned; at any rate when sublimate is used in the way described, viz., in a vaginal douche of 1 in 2,000 at a temperature of 115 F. immediately after the delivery of the placenta, and three similar douches subsequently at morning and evening. Afterward iodine is substituted. This is very different from strong intra-uterine douches and could easily be car-

ried out in general practice. Dr. Godson requires one-half gallon of a solution of 1 in 1.000 to be at the house, labelled "To be used with an equal part of hot water as a lotion," and this plan could always be adopted.

An important action for alleged negligence has been brought against Dr. Edwards, of Bangor, by a solicitor whose child died. The death was duly certified as from malignant sore throat, but the solicitor alleged that the diagnosis was wrong and that his child had diphtheria. Mr. Lennox Brown went down to support this contention. He had not seen the patient, but from what he heard was quite satisfied the child had malignant diphtheria. Dr. Edwards and Dr. Farley, who attended the child, both gave evidence that it was not diphtheria, and they were supported by Dr. Lloyd Roberts, consulting physician of the Manchester Infirmary and Dr. Ashby, physician to the same and lecturer on children's diseases at Owens College. The judge said there was no evidence that the defendant had not used reasonable care, and gave judgment for him with costs.

Lord Lister took a trip to Belfast last week to help Queen's College, on the occasion of the opening of the new buildings devoted to physiology and pathology. He could well speak in praise of these studies, and he expressed a hope one day to see a Pasteur institute in connection with the college. With this and the new hospital which will be completed in a few months Belfast will indeed be to the front. Lord Lister, according to the newspapers, said he hoped that the time will shortly come when Belfast will have its own university, a true teaching and graduating university on the lines of the Scottish and continental universities. He rejoiced to be present at the celebration of the jubilee of the college and had thoroughly enjoyed the proceedings.

LOW FEES AND DISPENSARY PRACTICES IN ENGLAND.

To the Editor of the Medical Record.
